Demand-Driven Automatic Control of Irrigation Channels

Abstract

Large-scale networks of reservoirs and open channels are widely used in agricultural set-

tings for distributing water to irrigators. A demand-driven approach to the automatic control of irrigation channels is described in this entry. The approach involves online measurement of water levels along the channel and distributed feedback control of flow regulation structures to manage the capacity to supply water off-takes under the power of gravity.

management

Introduction

Humans have engineered water distribution systems for millennia; e.g., see Mays (2010) and Ortloff (2009). Large-scale networks of open channels continue to be used widely for redirecting water from the environment to support food production. It is noted in UNESCO (2019) that, while only around 20% of the world's cultivated land is currently irrigated, this accounts for more than 40% of global food production. Furthermore, it is noted in this report that the yield of certain crops can double or even triple when supplemented with irrigation. Approximately 70% of the water diverted from rivers and groundwater worldwide goes to irrigation, but less than 60% of this is then used productively (Schultz et al. 2005). Water is not lost, because it remains part of the freshwater cycle. However, any water taken for irrigation is no longer available for other uses, such as maintaining environmental flows or supporting other human activities.

It is estimated that irrigation inefficiency is equally split between conveyance network losses and on-farm inefficiencies, although this can vary significantly from region to region and year to year. Pre-modernization losses in Australian irrigation networks were around 30% of water released at the source on average. The largest fraction of this (at around half) was due to oversupply (Marsden Jacob Associates 2003). Similar or higher conveyance losses have been

reported for Spain (Playan and Mateos 2004), Cyprus, Jordan, Egypt (Lamaddalen et al. 2004), and India (Puram and Sewa Bhawan 2014). The opportunity for improvement in the operation of irrigation network infrastructure is evidently large. The expected increase in demand for precision water delivery, in flow rate and timing, is also a driver for better management. The significance of this relates to food production pressures as the global population grows and living standards rise in developed and developing countries (Davis and Hirji 2003). With the expansion of channel networks in response to increasing demand for irrigation, and to the impacts of climate change, the modernization of operational practices is also relevant in terms of providing value for the often large public investment involved. The economic case for water efficiency is made in Water Resources Group (2009).

In the absence of constraints on the sources of water for an irrigation channel network, it is natural to oversupply, since a potential penalty for shortfalls is crop failure. For a channel that is operated at maximum flow capacity, off-takes to farms can be (in principle) scheduled subject to the supply limit alone, without much regard for the channel dynamics. However, this limits the flexibility with which farmers can conduct their business. Further, deviations from the schedule can lead to irrecoverable outflows at the bottom of the channel network, resulting in poor distribution efficiency. By contrast, an on-demand operating regime requires regulation of water levels at the gravity-powered supply points to farms. While this provides farmers with the flexibility needed for improving the efficiency of on-farm operations, it cannot be readily achieved under infrequent manual adjustment of the flow regulation structures along a channel. Moreover, proper consideration of the channel dynamics becomes important.

Advances in sensor, actuator, and telecommunication technologies underpin the scope for automating the operation of irrigation channel networks. Online measurement of water levels at the supply points along a channel enables the use of feedback control methods to automatically

adjust flow regulation structures in response to varying demand for off-take flows. The purpose of this entry is to present a so-called distant-downstream feedback control architecture. This architecture results in demand-driven release of water from the source and, thus, zero or specified outflow at the end of the channel. The underlying modelling and distributed control design framework is discussed, along with limitations regarding the spatial propagation of transients in response to changes in flow demand. Perspectives derived from long-term operation of such controllers on irrigation channels in southeastern Australia are also provided. To conclude, some directions of ongoing research are summarized.

Distributed Distant-Downstream Control Architecture

A top view of an irrigation channel network is shown in Fig. 1. Such networks often span thousands of square kilometers. Each channel is a cascade of open water reaches called pools, with lengths that can range from hundreds to thousands of meters. These are separated by flow regulation structures called gates. Figure 2 illustrates the side view of a pool with overshoot gates; the use of undershot gates is also common in practice. Each gate can be used to set the corresponding flow downstream, provided suffi-

ciently frequent adjustments can be made to the gate position relative to the upstream water level. Supply points to farms tend to be situated at the downstream ends of the pools. As such, the gravity-fed capacity of a pool to convey flow further along the channel and to supply farms locally is determined by the corresponding downstream water level.

Regulation of the downstream water level y_i in pool_{*i*} can be achieved by feedback control (Malaterre 1995; Schuurmans et al. 1999a; Weyer 2002; Mareels et al. 2005). An instance of such a control system adjusts the upstream inflow $u_i = \gamma_i h_i^{3/2}$ by manipulating the gate position p_i to set the head over the gate $h_i = y_{i-1} - p_i$, where the constant γ_i is a discharge coefficient. This control action is made a function of the water level error $e_i = r_i - y_i$ for the given reference set point r_i . A standard approach is to use integral action in the controller to ensure zero steady-state water-level error in response to step changes of the local off-take and downstream flow load disturbance to the closed loop. It is of note that information about the instantaneous downstream flow load is known, since it is the result of control action. Thus, it can be fed forward (upstream) to improve system-wide performance to some extent, as discussed below in line with the investigations reported in Li et al. (2005) and Cantoni et al. (2007). The architecture of such a control system is illustrated

Demand-Driven Automatic Control of Irrigation Channels, Fig. 1 Top view of an irrigation channel network

Demand-Driven Automatic Control of Irrigation Channels,

Fig. 2 Side view of an irrigation channel pool. (Adapted from Cantoni et al. 2007)

Demand-Driven Automatic Control of Irrigation Channels, Fig. 3 Distributed distant-downstream control architecture. (Adapted from Cantoni et al. 2007)

in Fig. 3. Subsystem P_i represents the dynamics of pool_{*i*}, with inflow u_i and outflow load $v_i + d_i$, in which d_i is the local off-take and v_i is the downstream flow. The subsystem C_i denotes the corresponding component of the distributed controller.

The start and end of an off-take changes the net flow into the corresponding pool. The transient water level error caused by this results in local control action, in order to adjust the upstream flow. This in turn changes the net flow into the pool immediately upstream, which results in further control action there, until the inflow at the top of the channel is adjusted to ultimately match the change in load. In this way, the release of upstream flow is demand driven. As such, under the so-called distant-downstream control architecture just described, it is possible to ensure specified (e.g., zero) outflow

at the end of channel. By contrast, alternative control architectures that rely on adjustment of the downstream gate of a pool to regulate the downstream water level do not exhibit this property. It is of note that similarly structured control systems play a role in the management of sewer networks (Marinaki and Papageorgiou 2005).

An approach to the design of the components of the distant-downstream control architecture is discussed below. From a practical perspective, an important feature of the approach relates to the scalability of the design process and maintainability of the control system. In particular, design of the distributed controllers is conducted on a pool-by-pool basis, using only local model information. Moreover, the implementation of the control system requires only localized information exchange from the downstream gate to

the upstream gate of each pool. Limitations on achievable performance under this purely reactive regime are also discussed.

Modelling Channel Dynamics for Control Design

A physics-based approach to modelling the dynamics of a pool leads to the so-called St Venant equations (Chaudry 2007; Litrico and Fromion 2009), given by

$$\frac{\partial A}{\partial t} + \frac{\partial Q}{\partial x} + q_l = 0, \quad (1)$$

$$\begin{aligned} \frac{\partial Q}{\partial t} + \left(\frac{gA}{B} - \frac{Q^2}{A^2} \right) \frac{\partial A}{\partial x} + 2 \frac{Q}{A} \frac{\partial Q}{\partial x} \\ + gA(S_f - S_0) = 0, \end{aligned} \quad (2)$$

where $A(x, t)$ is the cross section of water at time $t \geq 0$ and position $x \in [0, L]$ along the stretch of length L ; the total flow through this cross section is $Q(x, t)$; the outflow $q_l(x, t)$ per unit length accounts for off-takes; $B(x)$ is the bottom width; $S_0(x)$ is the per unit length longitudinal bottom slope; $S_f = n^2 Q^2 / A^2 R^{4/3}$ represents the friction slope, in which n is Manning's constant and R is the hydraulic radius; and g is gravitational acceleration. These are a one-dimensional version of the Navier-Stokes equations, representing conservation mass and momentum along the length of the pool. Accounting for channel state-dependent seepage and evaporation further complicates the model. As a first-order approximation, these effects can be lumped into $q_l(x, t)$.

The boundary conditions for (1)–(2) are $Q(0, t)$ and $Q(L, t)$. These are determined by the hydraulic characteristics and the positioning of the flow regulation structures at the upstream and downstream end of the pool, which provide communication between the adjacent stretches of open water along the channel. For an overshoot gate in free flow (i.e., not submerged), the sharp crested weir model is appropriate (Bos 1989): $Q(L, t) = \gamma h(t)^{3/2}$, where $h(t) = y(t) - p(t)$ is the head over the gate, $y(t) = f(A(L, t))$ is the downstream water level at $x = L$

(i.e., immediately upstream of the gate), and $p(t)$ is the position of the gate at time $t \geq 0$. The constant γ is a discharge coefficient.

The St Venant equations have been used for control system design (de Halleux et al. 2003; Litrico et al. 2005). However, this partial differential equation (PDE) model is of limited value in practice because it can be difficult to calibrate on the basis of observable data. Furthermore, it reflects more than is required from the perspective of regulating the downstream water levels; indeed, the water level and flow are predicted along the entire length of each pool. For the purpose of feedback controller design, it has been found that a much simpler grey-box model is more suitable (Schuurmans et al. 1995, 1999b; Weyer 2001).

With reference to Fig. 2, the grey-box model proposed in Weyer (2001) takes the form

$$\begin{aligned} \pi_i \left(\frac{d}{dt} \right) y_i(t) = \gamma_i h_i^{3/2}(t - \tau_i) \\ - \gamma_{i+1} h_{i+1}^{3/2}(t) - d_i(t), \end{aligned} \quad (3)$$

where y_i is the downstream water level in pool_{*i*}, the terms $h_i = y_{i-1} - p_i$ and $h_{i+1} = y_i - p_{i+1}$ are the head over the upstream and downstream gate, respectively, γ_i and γ_{i+1} are constant discharge parameters, d_i models the local off-take load, and τ_i is the time delay associated with surface wave propagation along the length of the pool. For a pool of up to several kilometers in length, the polynomial $\pi_i(\cdot)$ can be taken to be of third order, to yield an integrator mode for mass balance and a lightly damped oscillatory mode to capture the dominant standing wave. The model (3) is much simpler than the traditional St Venant equations (1)–(2). Its parameters can be readily calibrated to observed data by standard system identification techniques. It has been seen to explain experimental data very well (Weyer 2001; Ooi et al. 2005). Moreover, the model (3) is more tractable in terms of designing feedback controllers to achieve water level regulation under variable and uncertain load conditions. In fact, provided the local control-loop bandwidth lies below the dominant standing wave frequency, as

required anyway to achieve closed-loop stability in the presence of the related time delay, the first-order linear model

$$\alpha_i \frac{d}{dt} y_i(t) = u_i(t - \tau_i) - (v_i(t) + d_i(t)) \quad (4)$$

is adequate for control design. Here, α_i relates to the pool surface area, $u_i(t) = \gamma_i h_i(t)^{3/2}$ is the upstream inflow, and $v_i(t) = \gamma_{i+1} h_{i+1}(t)^{3/2}$ is the downstream flow load at time $t \geq 0$.

Design and Limitations of Distributed Distant-Downstream Controllers

Taking the Laplace transform of (4) yields the frequency domain model

$$P_i : \quad Y_i(s) = \frac{1}{s \alpha_i} \left(\exp(-s\tau_i) U_i(s) - V_i(s) - D_i(s) \right), \quad (5)$$

where $V_i(s) = U_{i+1}(s)$ for $i \in \{1, \dots, N-1\}$, with the boundary condition $V_N(s) = \mathcal{L}[v_n](s)$ for the specified time-domain outflow v_n at the end of the channel; e.g., $v_n = 0$ for no outflow.

Given such a model, frequency-domain loop-shaping principles of the kind described in Doyle et al. (1992) and Åström and Murray (2010), for example, can be applied on a pool-by-pool basis, which is scalable and advantageous from an engineering maintenance perspective. With reference to Fig. 3, this classical approach is used in practice to design decentralized PI feedback compensators of the form

$$C_i : \quad U_i(s) = \frac{\kappa_i (1 + s\phi_i)}{s (1 + s\psi_i)} E_i(s), \quad (6)$$

where $E_i(s) = Y_i(s) - R_i(s)$ and $R_i(s) = \rho_i/s$ for the reference water level $\rho_i > 0$. The compensator parameters ϕ_i, ψ_i, κ_i are positive constants selected to achieve closed-loop stability and desirable transient performance in response changes in the load $V_i + D_i$ and to achieve robustness to high-frequency modelling uncertainty. Specifically, the compensator

parameters κ_i and ϕ_i are set to introduce phase lead at the desired loop gain bandwidth in line with transient performance specifications and to accommodate a level of uncertainty in the delay. Additional roll-off beyond this to ensure low gain at the dominant wave frequency is achieved by appropriate selection of the constant ψ_i . By the internal model principle, step load disturbances are rejected in steady state along the channel because of integral action in the controller (see the pole at $s = 0$). The feedback control system effectively measures the off-take load and sets the flows over upstream gates in order to match the supply to the demand.

It is important to note that, in addition to the local transient response to changes in load, the closed-loop system for the channel as a whole exhibits spatial dynamics. Specifically, transient responses to changes in off-take load propagate upstream. Control action taken in response to a change in load locally acts as disturbance on the upstream pool (Li et al. 2005; Cantoni et al. 2007). This disturbance is known and can be fed forward by using distributed compensators of the form

$$C_i : \quad U_i(s) = \frac{\kappa_i (1 + s\phi_i)}{s (1 + s\psi_i)} E_i(s) + F_i(s) W_i(s),$$

where $W_i(s) = U_{i+1}(s)$. In practice, a simple constant feedforward compensator $F_i(s) = \varphi$ with $\varphi \in (0, 1)$ is used. This can yield better spatial transient propagation characteristics relative to the case of $F_i(s) = 0$. However, the requirement of zero steady-state error for on/off type off-takes leads to fundamental limitations. In particular, string instability of the kind that arises in homogeneous vehicle platoons (e.g., see Seiler et al. 2004) can be observed in sections of channel comprising cascades of pools with similar dynamics (Li et al. 2005; Cantoni et al. 2007). Specifically, there can be amplification of the peak flows over the gates as the transient response propagates upstream toward the source of the channel. Alternative distributed distant-downstream compensator forms that sacrifice steady-state water level error to achieve string stable dynamics are considered in Soltanian and

Cantoni (2015). In practice, variation in the dynamics of adjacent pools tends to moderate string stability issues. Practical implementations also include anti-windup compensation for managing flow regulation structure limits; e.g., see Zaccarian et al. (2007) and Li and Cantoni (2007).

Results from Operational Channels

The focus of the Northern Victoria Irrigation Renewal Project (NVIRP 2009) was to achieve significant water efficiency gains in Australia's largest irrigated agricultural region. The project aim was to balance the needs of rural communities, to preserve food production and to improve agricultural sustainability and conservation of natural ecology. The on-demand system described above was implemented in the upgrade of the gravity-fed network in the Goulburn Murray Irrigation District (GMID). Similar projects are underway elsewhere in Australia and around the globe, including in the USA, China, and India.

The operational losses in one of the first Australian irrigation networks to be automated are displayed in Fig. 4 for the period 1998–2016, based on data from Hawke (2016). Losses

are shown in per-unit, with 100 representing pre-automation losses under normal allocation conditions; note that the values of less than 100 seen in 1999, 2000 and 2003 correspond to seasons in which the allocation of water for irrigation was less than usual. Before 2004, classical manual operation with SCADA support was employed across the district. The period 2002–2003 included the major upgrade of all regulating structures and off-take points in the channels and deployment of the distributed distant-downstream control system described above. This control system was made operational from the irrigation season 2004 onward. This operating regime is autonomous in the sense that, based on the online measurement of water levels across the network, the control system is entirely responsible for meeting water demand at the requested outlets. Automation resulted directly in a 50% reduction in water losses. Similar improvements in distribution efficiency are reported for the whole GMID in the recent audit report (Cardno 2017), which constitutes one of the largest deployments of the technology to date.

As operators became more familiar with the capacity of the on-demand system, and the data furnished by the system was used to better understand seepage losses, for example, small and steady improvements ensued over the decade 2004–14; see Fig. 4. This nudged annual losses to about 30% of pre-automation losses. Importantly, it was found that a small number of the main channels were responsible for the major seepage losses, which allowed management to direct the maintenance money to target these channels for lining and general upgrades. In 2014, the district board instigated a major data mining and optimization task force that exploited the last decade of automation data to find better scheduling guidelines and water set points for the entire system. It was further motivated to do this, because under automation the behavior of irrigators changed significantly as compared to the previous system. So the new norm of supply and demand conditions required a new operational irrigation regime for the controller to implement. This work resulted in a further 10% reduction in

Demand-Driven Automatic Control of Irrigation Channels, Fig. 4 Annually operational losses in per unit from 1998 to 2016 for an automated irrigation district in southeast Australia. (Adapted from Hawke 2016)

annual losses, bringing losses to about 16% of pre-automation days.

It has been found that the water regulating structures are moving on average every 10 min, across the entire season, compared to half-daily or even less frequent adjustment under manual operation. Moreover, in the automation regime, the behavior of the farmers with respect to using irrigation water has changed. The flexibility offered by water on demand allows planning in response to crop needs and the pursuit of better yields for their particular farm. Often larger flows over a shorter supply period are requested, which has in turn led to a redesign of onto-farm off-takes to cater for these conditions. The typical flow conditions on the channels are totally different from those observed before automation.

Summary and Future Directions

The technology and ideas described above have been patented (e.g., see Aughton et al. 2002a,b) and made commercially available through Rubicon Water (Pty Ltd). Automatic control of the kind described transforms gravity-fed open channel irrigation networks to enable near on-demand water distribution.

Demand-driven water management improves not only the conveyance efficiency, from reservoir to farm, but also farm water efficiency. Indeed it reduces the farmer's risk in crop management considerably. The ability to time water in response to crop needs improves crop yield and reduces fertilizer consumption. This improves the economic productivity of the farm, which is perhaps the ultimate driver for the implementation of channel network automation. The reduction in fertilizer requirements, combined with a reduction in on-farm water runoff, brings with it a welcome reduction in environmental stress.

The information infrastructure underpinning channel network automation also provides operators with a comprehensive set of data about water flows, water consumption, and water levels across the entire irrigation district. This allows for better management of the channel infrastructure and the available water resource. This data can form the

basis for how the limited available water resource can be optimally used (within the limitations of the infrastructure) to trade off water needs, incorporating rural, agricultural, urban, and ecological perspectives. This becomes a very worthwhile pursuit within the context of an economic market for water trading.

The demand-driven automatic control system described above regulates water levels to set points in the face of varying water demand. The water level set points are governed by the system operator. One can thus conceive supervisory control systems for determining set points that are suited to the operational mode at hand, as patented in Choy et al. (2013), for example. This can range from the use of short-term demand forecasts to improve the limitations of purely reactive feedback control at the lowest level, to methods for emptying channels (for maintenance), or filling channels (after maintenance or for ecological reasons), or passing water at maximum flow. It is but a small step, to envisage a supervisory control strategy that exploits the irrigation infrastructure for flood mitigation, spreading water over a larger area, storing a significant amount in channels, but more importantly routing water away to areas where excess water causes the least damage. Given the economic impact, such flood mitigation control strategies deserve much more attention.

Supervisory control problems of the kind just described can be addressed by using receding horizon optimal control techniques. For example, see van Overloop (2006). However, it transpires that model predictive control (MPC) can become computationally challenging when all of the physical constraints are incorporated for the channel network as a whole in a global formulation of such a scheme. Finding good structure exploiting methods for solving large-scale problems is an avenue for future research. Initial work in this direction is reported in Cantoni et al. (2017) and Zafar et al. (2019), for example. Alternative multi-agent approaches that seek to contain the size of the individual optimization problems to be solved, and the communication overhead required for cooperation, are considered in Negenborn et al. (2009) and Fele et al. (2014),

for example. Of course, there is also the challenge of managing the inevitable uncertainty in demand forecasts that may be available for use in the supervisory problem. See Nasir et al. (2019) for work on a stochastic approach to this issue.

In the end, the only reason water is required for irrigation is to grow crops. How to best manage the feedback loop from available water to crop production and the human lifestyle it supports is the real question that has to be addressed. This belongs to *circular economics* thinking and goes well beyond mere automation. It brings into focus new ways of farming, new crops, energy consumption, and population health issues. Nevertheless, automation will remain the key technology to pursue productivity and efficiency gains, as illustrated in the present context of improving gravity-fed open-channel water distribution.

Descriptor System Techniques and Software Tools

Andreas Varga
Gilching, Germany

Abstract

The role of the descriptor system representation as a basis for reliable numerical computations for system analysis and synthesis, and in particular, for the manipulation of rational matrices, is discussed and available robust numerical software tools are described.

Keywords

CACSD · Modeling · Differential-algebraic systems · Rational matrices · Numerical analysis · Software tools

Introduction

A *linear time-invariant* (LTI) continuous-time descriptor system is described by the equations

$$\begin{aligned} E\dot{x}(t) &= Ax(t) + Bu(t), \\ y(t) &= Cx(t) + Du(t), \end{aligned} \quad (1)$$

where $x(t) \in \mathbb{R}^n$ is the state vector, $u(t) \in \mathbb{R}^m$ is the input vector, $y(t) \in \mathbb{R}^p$ is the output vector, and $A, E \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, $C \in \mathbb{R}^{p \times n}$, $D \in \mathbb{R}^{p \times m}$. The square matrix E is possibly singular, but we assume that the linear matrix pencil $A - \lambda E$, with λ a complex parameter, is regular (i.e., $\exists \lambda \in \mathbb{C}$ such that $\det(A - \lambda E) \neq 0$). A LTI discrete-time descriptor system has the form

$$\begin{aligned} Ex(k+1) &= Ax(k) + Bu(k), \\ y(k) &= Cx(k) + Du(k). \end{aligned} \quad (2)$$

Descriptor system representations of the forms (1) and (2) are the most general descriptions of LTI systems. Standard LTI state-space systems correspond to the case $E = I_n$. We will alternatively denote the LTI descriptor systems (1) and (2) with the quadruples $(A - \lambda E, B, C, D)$ or (A, B, C, D) if $E = I_n$.

Continuous-time descriptor systems frequently arise when modeling interconnected systems involving linear differential equations and algebraic relations, and are also common in modeling constrained mechanical systems (e.g., contact problems). Discrete-time descriptor representations are encountered in the modeling of some economic processes. The descriptor system representation is instrumental in devising general computational procedures (even for standard LTI systems), whose intermediary steps involve operations leading to descriptor representations (e.g., system inversion or system conjugation in the discrete-time case).

The input-output behavior of the LTI systems (1) and (2) can be described in the form

$$\mathbf{y}(\lambda) = G(\lambda)\mathbf{u}(\lambda), \quad (3)$$

where $\mathbf{u}(\lambda)$ and $\mathbf{y}(\lambda)$ are the transformed input and output vectors, using, in the continuous-time

case, the Laplace transform with $\lambda = s$, and, in the discrete-time case, the Z-transform with $\lambda = z$, and where

$$G(\lambda) = C(A - \lambda E)^{-1}B + D \quad (4)$$

is the *transfer function matrix* (TFM) of the system. The TFM $G(\lambda)$ is a rational matrix having entries which are rational functions in the complex variable λ (i.e., ratios of two polynomials in λ). $G(\lambda)$ is *proper* (*strictly proper*) if each entry of $G(\lambda)$ has the degree of its denominator larger than or equal to (larger than) the degree of its numerator. If E is singular, then $G(\lambda)$ could have entries with the degrees of numerators exceeding the degrees of the corresponding denominators, in which case $G(\lambda)$ is *improper*. We will use the alternative notation

$$G(\lambda) := \left[\begin{array}{c|c} A - \lambda E & B \\ \hline C & D \end{array} \right], \quad (5)$$

to relate the TFM $G(\lambda)$ in (4) to a particular quadruple $(A - \lambda E, B, C, D)$.

An important application of LTI descriptor systems is to allow the numerically reliable manipulation of rational matrices (in particular, also of polynomial matrices). This is possible, because for any rational matrix $G(\lambda)$, there exists a quadruple $(A - \lambda E, B, C, D)$ with $A - \lambda E$ regular, such that (4) is fulfilled. Determining the matrices A, E, B, C , and D for a given rational matrix $G(\lambda)$ is known as the realization problem, and the quadruple $(A - \lambda E, B, C, D)$ is called a descriptor realization of $G(\lambda)$. The solution of the realization problem is not unique. For example, if U and V are invertible matrices of the same order as A , then two realizations $(A - \lambda E, B, C, D)$ and $(\tilde{A} - \lambda \tilde{E}, \tilde{B}, \tilde{C}, D)$ related as

$$\tilde{A} - \lambda \tilde{E} = U(A - \lambda E)V, \quad \tilde{B} = UB, \quad \tilde{C} = CV, \quad (6)$$

have the same TFM. The relations (6) define a (restricted) *similarity transformation* between the two descriptor system representations. Performing similarity transformations is a basic tool to manipulate descriptor system representations. An important aspect is the existence of minimal

realizations, which are descriptor realizations with the smallest possible state dimension n . The characterization of minimal descriptor realizations in terms of systems properties (i.e., controllability, observability, absence of non-dynamic modes) is done in Verghese et al. (1981). To simplify the presentation, we will assume in most of the cases discussed that the employed realizations of rational matrices are minimal.

Complex synthesis approaches of controllers and filters for plants modeled as LTI systems are often described as conceptual computational procedures in terms of input-output representations via TFMs. Since the manipulation of rational matrices is numerically not advisable because of the potential high sensitivity of polynomial based representations, it is generally accepted that the manipulation of rational matrices is best performed via their equivalent descriptor realizations. In what follows, we focus on discussing a selection of descriptor system techniques which are frequently encountered as computational blocks of the synthesis procedures. However, we refrain from discussing computational details, which can be found in the cited references. We conclude our presentation with a short overview of available software tools for descriptor systems.

Basics of Manipulating Rational Matrices

In this section, we present the basic manipulations of rational matrices, which represent the building blocks of more involved manipulations.

Basic Operations

We consider some operations involving a single TFM $G(\lambda)$ with the descriptor realization $(A - \lambda E, B, C, D)$. The *transposed* TFM $G^T(\lambda)$ corresponds to the *dual descriptor system* with the realization

$$G^T(\lambda) = \left[\begin{array}{c|c} A^T - \lambda E^T & C^T \\ \hline B^T & D^T \end{array} \right].$$

If $G(\lambda)$ is invertible, then an inversion free realization of the *inverse* TFM $G^{-1}(\lambda)$ is given by

$$G^{-1}(\lambda) = \left[\begin{array}{c|c} A - \lambda E & B \\ \hline C & D \\ \hline 0 & -I \end{array} \right].$$

This realization is not minimal, even if the original realization is minimal. However, if D is invertible, then an alternative realization of the inverse is

$$G^{-1}(\lambda) = \left[\begin{array}{c|c} A - BD^{-1}C - \lambda E & -BD^{-1} \\ \hline D^{-1}C & D^{-1} \end{array} \right],$$

which is minimal if the original realization is minimal. Notice that this operation may generally lead to an improper inverse even for standard state-space realizations (A, B, C, D) with singular D .

The *conjugate* (or *adjoint*) TFM $G^\sim(\lambda)$ is defined in the continuous-time case as $G^\sim(s) = G^T(-s)$ and has the realization

$$G^\sim(s) = \left[\begin{array}{c|c} -A^T - sE^T & C^T \\ \hline -B^T & D^T \end{array} \right],$$

while in the discrete-time case $G^\sim(z) = G^T(z^{-1})$ and has the realization

$$G^\sim(z) = \left[\begin{array}{c|c} E^T - zA^T & 0 \\ \hline zB^T & I \\ \hline 0 & I \end{array} \right].$$

This operation may generally lead to a conjugate system with improper $G^\sim(z)$, for a standard discrete-time state-space realization (A, B, C, D) with singular A .

Basic Couplings

Consider now two LTI systems with the rational TFMs $G_1(\lambda)$ and $G_2(\lambda)$, having the descriptor realizations $(A_1 - \lambda E_1, B_1, C_1, D_1)$ and $(A_2 - \lambda E_2, B_2, C_2, D_2)$, respectively. The product $G_1(\lambda)G_2(\lambda)$ represents the *series coupling* of the two systems and has the descriptor realization

$$G_1(\lambda)G_2(\lambda) := \left[\begin{array}{cc|c} A_1 - \lambda E_1 & B_1 C_2 & B_1 D_2 \\ 0 & A_2 - \lambda E_2 & B_2 \\ \hline C_1 & D_1 C_2 & D_1 D_2 \end{array} \right].$$

The *parallel coupling* corresponds to the sum $G_1(\lambda) + G_2(\lambda)$ and has the realization

$$G_1(\lambda) + G_2(\lambda) := \left[\begin{array}{cc|c} A_1 - \lambda E_1 & 0 & B_1 \\ 0 & A_2 - \lambda E_2 & B_2 \\ \hline C_1 & C_2 & D_1 + D_2 \end{array} \right].$$

The *column concatenation* of the two systems corresponds to building $\begin{bmatrix} G_1(\lambda) \\ G_2(\lambda) \end{bmatrix}$ and has the realization

$$\begin{bmatrix} G_1(\lambda) \\ G_2(\lambda) \end{bmatrix} = \left[\begin{array}{cc|c} A_1 - \lambda E_1 & 0 & B_1 \\ 0 & A_2 - \lambda E_2 & B_2 \\ \hline C_1 & 0 & D_1 \\ 0 & C_2 & D_2 \end{array} \right].$$

Similar realizations for the *row concatenation* and *diagonal stacking* of two systems result, using straightforward extensions of the standard systems case.

Canonical Forms of Linear Pencils

The main appeal of descriptor system techniques lies in their ability to address various analysis and synthesis problems of LTI systems in the most general setting, both from theoretical and computational standpoints. The basic mathematical ingredients for addressing analysis and synthesis problems of descriptor systems are two canonical forms of linear matrix pencils: the *Weierstrass canonical form* of a regular pencil and the *Kronecker canonical form* of a singular pencil. For a given a linear pencil $M - \lambda N$ (regular or singular), the corresponding canonical form $\tilde{M} - \lambda \tilde{N}$ can be obtained using a pencil similarity transformation of the form $\tilde{M} - \lambda \tilde{N} = U(M - \lambda N)V$, where U and V are suitable invertible matrices.

If the pencil $M - \lambda N$ is regular and $M, N \in \mathbb{C}^{n \times n}$, then, there exist invertible matrices $U \in \mathbb{C}^{n \times n}$ and $V \in \mathbb{C}^{n \times n}$ such that

$$U(M - \lambda N)V = \begin{bmatrix} J_f - \lambda I & 0 \\ 0 & I - \lambda J_\infty \end{bmatrix}, \quad (7)$$

where J_f is in a (complex) Jordan canonical form

$$J_f = \text{diag}(J_{s_1}(\lambda_1), J_{s_2}(\lambda_2), \dots, J_{s_k}(\lambda_k)), \quad (8)$$

with $J_{s_i}(\lambda_i)$ an elementary $s_i \times s_i$ Jordan block of the form

$$J_{s_i}(\lambda_i) = \begin{bmatrix} \lambda_i & 1 & & \\ & \lambda_i & \ddots & \\ & & \ddots & 1 \\ & & & \lambda_i \end{bmatrix}$$

and J_∞ is nilpotent and has the (nilpotent) Jordan form

$$J_\infty = \text{diag}(J_{s_1^\infty}(0), J_{s_2^\infty}(0), \dots, J_{s_h^\infty}(0)). \quad (9)$$

The Weierstrass canonical form (7) exhibits the finite and infinite eigenvalues of the pencil $M - \lambda N$. Overall, by including all multiplicities, there are $n_f = \sum_{i=1}^k s_i$ *finite eigenvalues* and $n_\infty = \sum_{i=1}^h s_i^\infty$ *infinite eigenvalues*. Infinite eigenvalues with $s_i^\infty = 1$ are called *simple infinite eigenvalues*. If M and N are real matrices, then there exist real matrices U and V such that the pencil $U(M - \lambda N)V$ is in a *real Weierstrass canonical form*, where the only difference is that J_f is in a real Jordan form. In this form, the elementary real Jordan blocks correspond to pairs of complex conjugate eigenvalues. If $N = I$, then all eigenvalues are finite and J_f in the Weierstrass form is simply the (real) Jordan form of M . The transformation matrices can be chosen such that $U = V^{-1}$.

If $M - \lambda N$ is an arbitrary (singular) pencil with $M, N \in \mathbb{C}^{m \times n}$, then, there exist invertible matrices $U \in \mathbb{C}^{m \times m}$ and $V \in \mathbb{C}^{n \times n}$ such that

$$U(M - \lambda N)V = \begin{bmatrix} K_r(\lambda) & & \\ & K_{reg}(\lambda) & \\ & & K_l(\lambda) \end{bmatrix}, \quad (10)$$

where:

- (1) The full row rank pencil $K_r(\lambda)$ has the form

$$K_r(\lambda) = \text{diag} (L_{\varepsilon_1}(\lambda), L_{\varepsilon_2}(\lambda), \dots, L_{\varepsilon_{v_r}}(\lambda)),$$

with $L_i(\lambda)$ ($i \geq 0$) an $i \times (i + 1)$ bidiagonal pencil of form

$$L_i(\lambda) = \begin{bmatrix} -\lambda & 1 & & \\ & \ddots & \ddots & \\ & & -\lambda & 1 \end{bmatrix}; \quad (11)$$

- (2) The regular pencil $K_{reg}(\lambda)$ is in a Weierstrass canonical form

$$K_{reg}(\lambda) = \begin{bmatrix} \tilde{J}_f - \lambda I & \\ & I - \lambda \tilde{J}_\infty \end{bmatrix},$$

with $\tilde{J}_f$ in a (complex) Jordan canonical form as in (8) and with $\tilde{J}_\infty$ in a nilpotent Jordan form as in (9);

- (3) The full column rank $K_l(\lambda)$ has the form

$$K_l(\lambda) = \text{diag} (L_{\eta_1}^T(\lambda), L_{\eta_2}^T(\lambda), \dots, L_{\eta_{v_l}}^T(\lambda)).$$

As it is apparent from (10), the Kronecker canonical form exhibits the right and left singular structures of the pencil $M - \lambda N$ via the full row rank block $K_r(\lambda)$ and full column rank block $K_l(\lambda)$, respectively, and the eigenvalue structure via the regular pencil $K_{reg}(\lambda)$. The full row rank pencil $K_r(\lambda)$ is $n_r \times (n_r + v_r)$, where $n_r = \sum_{i=1}^{v_r} \varepsilon_i$, the full column rank pencil $K_l(\lambda)$ is $(n_l + v_l) \times n_l$, where $n_l = \sum_{j=1}^{v_l} \eta_j$, while the regular pencil $K_{reg}(\lambda)$ is $n_{reg} \times n_{reg}$, with $n_{reg} = \tilde{n}_f + \tilde{n}_\infty$, where $\tilde{n}_f$ is the number of eigenvalues of J_f and $\tilde{n}_\infty$ is the number of infinite eigenvalues of $I - \lambda \tilde{J}_\infty$ (or equivalently the number of null eigenvalues of $\tilde{J}_\infty$). The normal rank r of the pencil $M - \lambda N$ results as

$$r := \text{rank}(M - \lambda N) = n_r + \tilde{n}_f + \tilde{n}_\infty + n_l.$$

If $M - \lambda N$ is regular, then there are no left- and right-Kronecker structures, and the Kronecker

canonical form is simply the Weierstrass canonical form.

The reduction of matrix pencils to the Weierstrass or Kronecker canonical forms generally involves the use of non-orthogonal, possibly ill-conditioned, transformation matrices. Therefore, the computation of these forms must be avoided when devising numerically reliable algorithms for descriptor systems. Alternative condensed forms, as the (ordered) generalized real Schur form of a regular pencil or various Kronecker-like forms of singular pencils, can be determined by using exclusively perfectly conditioned orthogonal transformations and can be always used instead of the Weierstrass or Kronecker canonical forms, respectively, in addressing the computational issues of descriptor systems.

Advanced Descriptor Techniques

In this section we discuss a selection of problems involving rational matrices, whose solutions involve the use of advanced descriptor system manipulation techniques. These techniques are instrumental in addressing controller and filter synthesis problems in the most general setting by using numerically reliable algorithms for the reduction of linear matrix pencils to appropriate condensed forms.

Normal Rank

The *normal rank* of a $p \times m$ rational matrix $G(\lambda)$, which we denote by $\text{rank } G(\lambda)$, is the maximal number of linearly independent rows (or columns) over the field of rational functions $\mathbb{R}(\lambda)$. It can be shown that the normal rank of $G(\lambda)$ is the maximally possible rank of the complex matrix $G(\lambda)$ for all values of $\lambda \in \mathbb{C}$ such that $G(\lambda)$ has finite norm. For the calculation of the normal rank r of $G(\lambda)$ in terms of its descriptor realization $(A - \lambda E, B, C, D)$, we use the relation

$$r = \text{rank } S(\lambda) - n,$$

where $\text{rank } S(\lambda)$ is the normal rank of the system matrix pencil $S(\lambda)$ defined as

$$S(\lambda) := \begin{bmatrix} A - \lambda E & B \\ C & D \end{bmatrix} \quad (12)$$

and n is the order of the descriptor state-space realization. The normal rank r can be easily determined from the Kronecker form of the pencil $S(\lambda)$ as

$$r := n_r + n_{reg} + n_l - n,$$

where n_r , n_{reg} , and n_l defines the normal ranks of $K_r(\lambda)$, $K_{reg}(\lambda)$, and $K_l(\lambda)$, respectively, in the Kronecker form (10) of $S(\lambda)$.

Poles and Zeros

The poles of $G(\lambda)$ are related to $\Lambda(A - \lambda E)$, the eigenvalues of the *pole pencil* $A - \lambda E$ (also known as the generalized eigenvalues of the pair (A, E)). For a minimal realization $(A - \lambda E, B, C, D)$ of $G(\lambda)$, the finite poles of $G(\lambda)$ are the $n_{p,f}$ finite eigenvalues in the Weierstrass canonical form of the regular pencil $A - \lambda E$, while the number of infinite poles is given by $n_{p,\infty} = \sum_{i=1}^h (s_i^\infty - 1)$, where s_i^∞ is the multiplicity of the i -th infinite eigenvalue. The infinite eigenvalues of multiplicity ones are the so-called non-dynamic modes. The McMillan degree of $G(\lambda)$, denoted by $\delta(G(\lambda))$, is the total number of poles $n_p := n_{p,f} + n_{p,\infty}$ of $G(\lambda)$

$$\delta(G(\lambda)) := n_p$$

and satisfies $\delta(G(\lambda)) \leq n$. A *proper* $G(\lambda)$ has only finite poles.

A proper $G(\lambda)$ is *stable* if all its poles belong to the appropriate stable region $\mathbb{C}_s \subset \mathbb{C}$, where $\mathbb{C}_s$ is the open left half plane of $\mathbb{C}$, for a continuous-time system, and the interior of the unit circle centered in the origin, for a discrete-time system. $G(\lambda)$ is *unstable* if it has at least one pole (finite or infinite) outside of the stability domain $\mathbb{C}_s$.

The zeros of $G(\lambda)$ are those complex values of λ (including also infinity), where the rank of the system matrix pencil (12) drops below its normal

rank $n + r$. Therefore, the zeros can be defined on the basis of the eigenvalues of the regular part $K_{reg}(\lambda)$ of the Kronecker form (10) of $S(\lambda)$. The finite zeros of $G(\lambda)$ are the $n_{z,f}$ finite eigenvalues of the regular pencil $K_{reg}(\lambda)$, while $n_{z,\infty}$, the total number of infinite zeros, is the sum of multiplicities of infinite zeros, which are defined by the multiplicities of infinite eigenvalues of $K_{reg}(\lambda)$ minus one. The total number of zeros is $n_z := n_{z,f} + n_{z,\infty}$. A proper and stable $G(z)$ is *minimum-phase* if all its zeros are finite and stable.

The number of poles and zeros of $G(\lambda)$ satisfy the relation

$$n_p = n_z + n_l + n_r,$$

where n_r and n_l are the normal ranks of $K_r(\lambda)$ and $K_l(\lambda)$, respectively, in the Kronecker form (10) of $S(\lambda)$.

Rational Nullspace Bases

Let $G(\lambda)$ be a $p \times m$ rational matrix of normal rank r and let $(A - \lambda E, B, C, D)$ be a minimal descriptor realization of $G(\lambda)$. The set of $1 \times p$ rational (row) vectors $\{v(\lambda)\}$ satisfying $v(\lambda)G(\lambda) = 0$ is a linear space, called the *left nullspace* of $G(\lambda)$, and has dimension $p - r$. Analogously, the set of $m \times 1$ rational (column) vectors $\{w(\lambda)\}$ satisfying $G(\lambda)w(\lambda) = 0$ is a linear space, called the *right nullspace* of $G(\lambda)$, and has dimension $m - r$.

The $p - r$ rows of a $(p - r) \times p$ rational matrix $N_l(\lambda)$ satisfying $N_l(\lambda)G(\lambda) = 0$ is a basis of the left nullspace of $G(\lambda)$, provided $N_l(\lambda)$ has full row rank. Analogously, the $m - r$ columns of a $m \times (m - r)$ rational matrix $N_r(\lambda)$ satisfying $G(\lambda)N_r(\lambda) = 0$ is a basis of the right nullspace of $G(\lambda)$, provided $N_r(\lambda)$ has full column rank. The determination of a rational left nullspace basis $N_l(\lambda)$ of $G(\lambda)$ can be easily turned into the problem of determining a rational basis of the system matrix $S(\lambda)$. Let $M_l(\lambda)$ be a suitable rational matrix such that

$$Y_l(\lambda) := [M_l(\lambda) \ N_l(\lambda)] \quad (13)$$

is a left nullspace basis of the associated system matrix pencil $S(\lambda)$ (12). Thus, to determine $N_l(\lambda)$ we can determine first $Y_l(\lambda)$, a left nullspace basis of $S(\lambda)$, and then $N_l(\lambda)$ results as

$$N_l(\lambda) = Y_l(\lambda) \begin{bmatrix} 0 \\ I_p \end{bmatrix}.$$

By duality, if $Y_r(\lambda)$ is a right nullspace basis of $S(\lambda)$, then a right nullspace basis of $G(\lambda)$ is given by

$$N_r(\lambda) = [0 \ I_m] Y_r(\lambda).$$

The Kronecker canonical form (10) of the system pencil $S(\lambda)$ in (12) allows to easily determine left and right nullspace bases of $G(\lambda)$. Let $\bar{S}(\lambda) = US(\lambda)V$ be the Kronecker canonical form (10) of $S(\lambda)$, where U and V are the respective left and right transformation matrices. If $\bar{Y}_l(\lambda)$ is a left nullspace basis of $\bar{S}(\lambda)$, then

$$N_l(\lambda) = \bar{Y}_l(\lambda)U \begin{bmatrix} 0 \\ I_p \end{bmatrix}. \quad (14)$$

Similarly, if $\bar{Y}_r(\lambda)$ is a right nullspace basis of $\bar{S}(\lambda)$ then

$$N_r(\lambda) = [0 \ I_m] V \bar{Y}_r(\lambda). \quad (15)$$

We choose $\bar{Y}_l(\lambda)$ of the form

$$\bar{Y}_l(\lambda) = [0 \ 0 \ \bar{Y}_{l,3}(\lambda)], \quad (16)$$

where $\bar{Y}_{l,3}(\lambda)$ satisfies $\bar{Y}_{l,3}(\lambda)K_l(\lambda) = 0$. Similarly, we choose $\bar{Y}_r(\lambda)$ of the form

$$\bar{Y}_r(\lambda) = \begin{bmatrix} \bar{Y}_{r,1}(\lambda) \\ 0 \\ 0 \end{bmatrix}, \quad (17)$$

where $\bar{Y}_{r,1}(\lambda)$ satisfies $K_r(\lambda)\bar{Y}_{r,1}(\lambda) = 0$. Both $\bar{Y}_{l,3}(\lambda)$ and $\bar{Y}_{r,1}(\lambda)$ can be determined as polynomial or rational matrices and the resulting bases are polynomial or rational as well.

Additive Decompositions

Let $G(\lambda)$ be a rational TFM with a descriptor system realization $G(\lambda) = (A - \lambda E, B, C, D)$.

Consider a disjunct partition of the complex plane $\mathbb{C}$ as

$$\mathbb{C} = \mathbb{C}_g \cup \mathbb{C}_b, \quad \mathbb{C}_g \cap \mathbb{C}_b = \emptyset, \quad (18)$$

where both $\mathbb{C}_g$ and $\mathbb{C}_b$ are symmetrically located with respect to the real axis, and $\mathbb{C}_g$ has at least one point on the real axis. Since $\mathbb{C}_g$ and $\mathbb{C}_b$ are disjoint, each pole of $G(\lambda)$ lies either in $\mathbb{C}_g$ or in $\mathbb{C}_b$. Using a similarity transformation of the form (6), we can determine an equivalent representation of $G(\lambda)$ with partitioned system matrices of the form

$$G(\lambda) = \left[\begin{array}{c|c} UAV - \lambda UEV & UB \\ \hline CV & D \end{array} \right] \quad (19)$$

$$= \left[\begin{array}{cc|c} A_g - \lambda E_g & 0 & B_g \\ 0 & A_b - \lambda E_b & B_b \\ \hline C_g & C_b & D \end{array} \right],$$

where $\Lambda(A_g - \lambda E_g) \subset \mathbb{C}_g$ and $\Lambda(A_b - \lambda E_b) \subset \mathbb{C}_b$. It follows that $G(\lambda)$ can be additively decomposed as

$$G(\lambda) = G_g(\lambda) + G_b(\lambda), \quad (20)$$

where

$$G_g(\lambda) = \left[\begin{array}{c|c} A_g - \lambda E_g & B_g \\ \hline C_g & D \end{array} \right],$$

$$G_b(\lambda) = \left[\begin{array}{c|c} A_b - \lambda E_b & B_b \\ \hline C_b & 0 \end{array} \right],$$

and $G_g(\lambda)$ has only poles in $\mathbb{C}_g$, while $G_b(\lambda)$ has only poles in $\mathbb{C}_b$. The spectral separation in (19) is automatically provided by the Weierstrass canonical form of the pole pencil $A - \lambda E$, where the diagonal Jordan blocks are suitably permuted to correspond to the desired eigenvalue splitting. This approach automatically leads to partial fraction expansions of $G_g(\lambda)$ and $G_b(\lambda)$.

Coprime Factorizations

Consider a disjunct partition (18) of the complex plane $\mathbb{C}$, where both $\mathbb{C}_g$ and $\mathbb{C}_b$ are symmetrically located with respect to the real axis, and such that

$\mathbb{C}_g$ has at least one point on the real axis. Any rational matrix $G(\lambda)$ can be expressed in a left fractional form

$$G(\lambda) = M^{-1}(\lambda)N(\lambda), \quad (21)$$

or in a right fractional form

$$G(\lambda) = N(\lambda)M^{-1}(\lambda), \quad (22)$$

where both the denominator factor $M(\lambda)$ and the numerator factor $N(\lambda)$ have only poles in $\mathbb{C}_g$. These fractional factorizations over a “good” domain of poles $\mathbb{C}_g$ are important in various observer, fault detection filter, or controller synthesis methods, because they allow to achieve the placement of all poles of a TFM $G(\lambda)$ in the domain $\mathbb{C}_g$ simply, by a premultiplication or postmultiplication of $G(\lambda)$ with a suitable $M(\lambda)$.

Of special interest are the so-called coprime factorizations, where the factors satisfy additional coprimeness conditions. A fractional representation of the form (21) is a *left coprime factorization* (LCF) of $G(\lambda)$ with respect to $\mathbb{C}_g$, if there exist $U(\lambda)$ and $V(\lambda)$ with poles only in $\mathbb{C}_g$ which satisfy the *Bezout identity*

$$M(\lambda)U(\lambda) + N(\lambda)V(\lambda) = I.$$

A fractional representation of the form (22) is a *right coprime factorization* (RCF) of $G(\lambda)$ with respect to $\mathbb{C}_g$, if there exist $U(\lambda)$ and $V(\lambda)$ with poles only in $\mathbb{C}_g$ which satisfy

$$U(\lambda)M(\lambda) + V(\lambda)N(\lambda) = I.$$

For the computation of a right coprime factorization of $G(\lambda)$ with a minimal descriptor realization $(A - \lambda E, B, C, D)$, it is sufficient to determine a state-feedback matrix F such that all finite eigenvalues in $\Lambda(A + BF - \lambda E)$ belong to $\mathbb{C}_g$, and all infinite eigenvalues in $\Lambda(A + BF - \lambda E)$ are simple. The descriptor realizations of the factors are given by

$$\begin{bmatrix} N(\lambda) \\ M(\lambda) \end{bmatrix} = \begin{bmatrix} A + BF - \lambda E & B \\ C + DF & D \\ F & I_m \end{bmatrix}.$$

Similarly, to determine a left coprime factorization, it is sufficient to determine an output-injection matrix K such that all finite eigenvalues in $\Lambda(A + KC - \lambda E)$ belong to $\mathbb{C}_g$ and all infinite eigenvalues in $\Lambda(A + KC - \lambda E)$ are simple. The descriptor realizations of the factors are given by

$$\begin{bmatrix} N(\lambda) & M(\lambda) \end{bmatrix} = \left[\begin{array}{c|cc} A + KC - \lambda E & B + KD & K \\ \hline C & D & I_p \end{array} \right].$$

An important class of coprime factorizations is the class of coprime factorizations with minimum-degree denominators. The McMillan degree of $G(\lambda)$ satisfies $\delta(G(\lambda)) = n_g + n_b$, where n_g and n_b are the number of poles of $G(\lambda)$ in $\mathbb{C}_g$ and $\mathbb{C}_b$, respectively. The denominator factor $M(\lambda)$ has the minimum-degree property if $\delta(M(\lambda)) = n_b$. Special classes of coprime factorizations, as the coprime factorizations with inner denominators or the normalized coprime factorizations, have important applications in solving various analysis and synthesis problems.

Linear Rational Matrix Equations

The solution of model-matching problems encountered in the synthesis of controllers or filters involves the solution of the linear rational matrix equation

$$G(\lambda)X(\lambda) = F(\lambda), \quad (23)$$

with $G(\lambda)$ a $p \times m$ rational matrix and $F(\lambda)$ a $p \times q$ rational matrix. This equation has a solution provided the compatibility condition

$$\text{rank } G(\lambda) = \text{rank}[G(\lambda) \ F(\lambda)] \quad (24)$$

is fulfilled. Assume $G(\lambda)$ and $F(\lambda)$ have descriptor realizations of the form

$$\begin{aligned} G(\lambda) &= \left[\begin{array}{c|c} A - \lambda E & B_G \\ \hline C & D_G \end{array} \right], \\ F(\lambda) &= \left[\begin{array}{c|c} A - \lambda E & B_F \\ \hline C & D_F \end{array} \right], \end{aligned}$$

which share the system pair $(A - \lambda E, C)$. It is easy to observe that any solution $X(\lambda)$ of (23) is also part of the solution $Y(\lambda) = \begin{bmatrix} W(\lambda) \\ X(\lambda) \end{bmatrix}$ of the linear polynomial equation

$$S_G(\lambda)Y(\lambda) = \begin{bmatrix} B_F \\ D_F \end{bmatrix}, \quad (25)$$

where $S_G(\lambda)$ is the associated system matrix pencil

$$S_G(\lambda) = \begin{bmatrix} A - \lambda E & B_G \\ C & D_G \end{bmatrix}. \quad (26)$$

Therefore, an alternative to solving (23) is to solve (25) for $Y(\lambda)$ instead and compute $X(\lambda)$ as

$$X(\lambda) = [0 \ I_p]Y(\lambda). \quad (27)$$

The compatibility condition (24) becomes

$$\begin{aligned} & \text{rank} \begin{bmatrix} A - \lambda E & B_G \\ C & D_G \end{bmatrix} \\ &= \text{rank} \begin{bmatrix} A - \lambda E & B_G & B_F \\ C & D_G & D_F \end{bmatrix}. \end{aligned}$$

If $G(\lambda)$ is invertible, a descriptor system realization of $X(\lambda)$ can be explicitly obtained as

$$X(\lambda) = \left[\begin{array}{cc|c} A - \lambda E & B_G & B_F \\ C & D_G & D_F \\ \hline 0 & -I_p & 0 \end{array} \right]. \quad (28)$$

The general solution of (23) can be expressed as

$$X(\lambda) = X_0(\lambda) + X_r(\lambda)Y(\lambda),$$

where $X_0(\lambda)$ is any particular solution of (23), $X_r(\lambda)$ is a rational basis matrix for the right nullspace of $G(\lambda)$, and $Y(\lambda)$ is an arbitrary rational matrix with suitable dimensions. General methods to determine both $X_0(\lambda)$ and $X_r(\lambda)$ can be devised by using the Kronecker canonical form of the associated system matrix pencil $S_G(\lambda)$ in (26). It is also possible to choose $Y(\lambda)$ to obtain special solutions, as for example, with least McMillan degree.

Software Tools

Several basic requirements are desirable when implementing robust software tools for numerical computations:

- employing exclusively numerically stable or numerically reliable algorithms;
- ensuring high computational efficiency;
- enforcing robustness against numerical exceptions (overflows, underflows) and poorly scaled data;
- ensuring ease of use, high portability, and high reusability.

The above requirements have been enforced in the development of high-performance linear algebra software libraries, such as BLAS (Dongarra et al. 1990), a collection of basic linear algebra subroutines, and LAPACK (Anderson et al. 1999), a comprehensive linear algebra package based on BLAS. These requirements have been also adopted to implement SLICOT (Benner et al. 1999; Van Huffel et al. 2004), a subroutine library for control theory, based primarily on BLAS and LAPACK. The general-purpose library LAPACK contains over 1300 subroutines and covers most of the basic linear algebra computations for solving systems of linear equations and eigenvalue problems. The release 4.5 of the specialized library SLICOT (<http://www.slicot.org/>) is a free software distributed under the GNU General Public License (GPL). The substantially enriched current release 5.6 is free for academic and non-commercial use and contains over 500 subroutines. SLICOT covers the basic computational problems for the analysis and design of linear control systems, such as linear system analysis and synthesis, filtering, identification, solution of matrix equations, model reduction, and system transformations. Of special interest is the comprehensive collection of routines for handling descriptor systems and for solving generalized linear matrix equations, as well as, the routines for computing various Kronecker-like forms. The subroutine libraries BLAS, LAPACK, and SLICOT have been originally implemented in the general-purpose

language Fortran 77 and, therefore, provide a high level of reusability, which allows their easy incorporation in user-friendly software environments, for example, MATLAB. In the case of MATLAB, selected LAPACK routines underlie the linear algebra functionalities, while the incorporation of selected SLICOT routines was possible via suitable gateways, as the provided *mex*-function interface.

The Control System Toolbox (CST) of MATLAB supports both descriptor system state-space models and input-output representations with improper rational TFMs and provides a rich functionality covering the basic system operations and couplings, model conversions, as well as some advanced functionality such as pole and zero computations, minimal realizations, and the solution of generalized Lyapunov and Riccati equations. However, most of the functions of the CST can only handle descriptor systems with proper TFMs and important functionality is currently lacking for handling the more general descriptor systems with improper TFMs, notably for determining the complete pole and zero structures or for computing minimal order realizations, to mention only a few of existing limitations.

To facilitate the implementation of the synthesis procedures of fault detection and isolation filters described in the book (Varga 2017), a new collection of freely available *m*-files, called the Descriptor System Tools (DSTOOLS), has been implemented for MATLAB. DSTOOLS is primarily intended to provide an extended functionality for both MATLAB (e.g., with matrix pencil manipulation methods for the computation of Kronecker-like forms) and for the CST by providing functions for minimal realization of descriptor systems, computation of pole and zero structures, computation of nullspace and range space bases, additive decompositions, several factorizations of rational matrices (e.g., coprime, full rank, inner-outer), evaluation of ν -gap distance, exact and approximate solution of linear rational matrix equations, eigenvalue assignment and stabilization via state feedback, etc. The approach used to develop DSTOOLS exploits MATLAB's matrix and object manipulation

features by means of a flexible and functionally rich collection of *m*-files, intended for noncritical computations, while simultaneously enforcing highly efficient and numerically sound computations via *mex*-functions (calling Fortran routines from SLICOT), to solve critical numerical problems requiring the use of structure-exploiting algorithms. An important aspect of implementing DSTOOLS was to ensure that standard systems are fully supported, using specific algorithms. In the same vein, all algorithms are available for both continuous- and discrete-time systems.

A precursor of DSTOOLS was the Descriptor Systems Toolbox for MATLAB, a proprietary software of the German Aerospace Center (DLR), developed between 1996 and 2006 (for the status of this toolbox around 2000, see Varga 2000). Some descriptor system functionality covering the basic manipulation of rational matrices is also available in the free, open-source software Scilab <http://scilab.org> and Octave <http://www.gnu.org/software/octave/>.

Recommended Reading

The theoretical aspects of descriptor systems are discussed in the two textbooks (Dai 1989; Duan 2010). For a thorough treatment of rational matrices in a system theoretical context two authoritative references are Kailath (1980) and Vidyasagar (2011). The book (Varga 2017) illustrates the use of descriptor system techniques to solve the synthesis problems of fault detection and isolation filters in the most general setting. Chapters 9 and 10 of this book describe in details the

presented descriptor system techniques for the manipulation of rational matrices and also give details on available numerically reliable algorithms. These algorithms form the basis of the implementation of the functions available in the DSTOOLS collection. A comprehensive documentation of DSTOOLS is available in arXiv (Varga 2018). An extended version of this entry, available in arXiv (Varga 2019), provides bibliographical references on the best computational methods and describes additional descriptor system techniques.

Deterministic Description of Biochemical Networks

Jörg Stelling and Hans-Michael Kaltenbach
ETH Zürich, Basel, Switzerland

Abstract

Mathematical models of living systems are often based on formal representations of the underlying reaction networks. Here, we present the basic concepts for the deterministic nonspatial treatment of such networks. We describe the most prominent approaches for steady-state and dynamic analysis using systems of ordinary differential equations.

Keywords

Michaelis-Menten kinetics · Reaction networks · Stoichiometry

Introduction

A biochemical network describes the interconversion of biochemical species such as proteins or metabolites by chemical reactions. Such networks are ubiquitous in living cells, where they are involved in a variety of cellular functions such as conversion of metabolites into energy or building material of the cell, detection and processing of external and internal signals of nutrient availability or environmental stress, and regulation of genetic programs for development.

Reaction Networks

A biochemical network can be modeled as a dynamic system with the chemical concentration of each species taken as the states and dynamics described by the changes in species concentrations as they are converted by reactions. Assuming that species are homogeneously distributed in the reaction volume and that copy numbers are sufficiently high, we may ignore spatial and stochastic effects and derive a system of ordinary differential equations (ODEs) to model the dynamics.

Formally, a biochemical network is given by r reactions $R_1, \dots, R_r$ acting on n different chemical species $S_1, \dots, S_n$. Reaction R_j is given by

where $\alpha_{i,j}, \beta_{i,j} \in \mathbb{N}$ are called the *molecularities* of the species in the reaction. Their differences form the *stoichiometric matrix* $\mathbf{N} = (\beta_{i,j} - \alpha_{i,j})_{i=1\dots n, j=1\dots r}$, with $N_{i,j}$ describing the net effect of one turnover of R_j on the copy number of species S_i . The j th column is also called the *stoichiometry* of reaction R_j . The system can be opened to an un-modeled environment by introducing inflow reactions $\emptyset \rightarrow S_i$ and outflow reactions $S_i \rightarrow \emptyset$.

For example, consider the following reaction network:

Here, an enzyme E (a protein that acts as a catalyst for biochemical reactions) binds to a substrate species S , forming an intermediate complex $E \cdot S$ and subsequently converting S into a product P . Note that the enzyme-substrate binding is reversible, while the conversion to a product is irreversible. This network contains $r = 3$ reactions interconverting $n = 4$ chemical species $S_1 = S$, $S_2 = P$, $S_3 = E$, and $S_4 = E \cdot S$. The stoichiometric matrix is

$$\mathbf{N} = \begin{pmatrix} -1 & +1 & 0 \\ 0 & 0 & +1 \\ -1 & +1 & +1 \\ +1 & -1 & -1 \end{pmatrix}.$$

Dynamics

Let $\mathbf{x}(t) = (x_1(t), \dots, x_n(t))^T$ be the vector of concentrations, that is, $x_i(t)$ is the concentration of S_i at time t . Abbreviating this state vector as $\mathbf{x}$ by dropping the explicit dependence on time, its dynamics is governed by a system of n ordinary

differential equations:

$$\frac{d}{dt} \mathbf{x} = \mathbf{N} \cdot \mathbf{v}(\mathbf{x}, \mathbf{p}). \quad (1)$$

Here, the *reaction rate* vector $\mathbf{v}(\mathbf{x}, \mathbf{p}) = (v_1(\mathbf{x}, \mathbf{p}_1), \dots, v_r(\mathbf{x}, \mathbf{p}_r))^T$ gives the rate of conversion of each reaction per unit-time as a function of the current system state and of a set of parameters $\mathbf{p}$.

A typical reaction rate is given by the *mass-action rate law*

$$v_j(\mathbf{x}, \mathbf{p}_j) = k_j \cdot \prod_{i=1}^n x_i^{\alpha_{i,j}},$$

where the rate constant $k_j > 0$ is the only parameter and the rate is proportional to the concentration of each species participating as an educt (consumed component) in the respective reaction.

Equation (1) decomposes the system into a time-independent and linear part described solely by the topology and stoichiometry of the reaction network via $\mathbf{N}$ and a dynamic and typically nonlinear part given by the reaction rate laws $\mathbf{v}(\cdot, \cdot)$. One can define a directed graph of the network with one vertex per state and take $\mathbf{N}$ as the (weighted) incidence matrix. Reaction rates are then properties of the resulting edges. In essence, the equation describes the change of each species' concentration as the sum of the current reaction rates. Each rate is weighted by the molecularity of the species in the corresponding reaction; it is negative if the species is consumed by the reaction and positive if it is produced.

Using mass-action kinetics throughout, and using the species name instead of the numeric subscript, the reaction rates and parameters of the example network are given by

$$v_1(\mathbf{x}, \mathbf{p}_1) = k_1 \cdot x_E(t) \cdot x_S(t)$$

$$v_2(\mathbf{x}, \mathbf{p}_2) = k_2 \cdot x_{E \cdot S}(t)$$

$$v_3(\mathbf{x}, \mathbf{p}_3) = k_3 \cdot x_{E \cdot S}(t)$$

$$\mathbf{p} = (k_1, k_2, k_3)$$

The system equations are then

$$\begin{aligned}\frac{d}{dt}x_S &= -k_1 \cdot x_S \cdot x_E + k_2 \cdot x_{E \cdot S} \\ \frac{d}{dt}x_P &= k_3 \cdot x_{E \cdot S} \\ \frac{d}{dt}x_E &= -k_1 \cdot x_S \cdot x_E + k_2 \cdot x_{E \cdot S} + k_3 \cdot x_{E \cdot S} \\ \frac{d}{dt}x_{E \cdot S} &= k_1 \cdot x_S \cdot x_E - k_2 \cdot x_{E \cdot S} - k_3 \cdot x_{E \cdot S} .\end{aligned}$$

Steady-State Analysis

A reaction network is in *steady state* if the production and consumption of each species are balanced. Steady-state concentrations $\mathbf{x}^*$ then satisfy the equation

$$\mathbf{0} = \mathbf{N} \cdot \mathbf{v}(\mathbf{x}^*, \mathbf{p}) .$$

Computing steady-state concentrations requires explicit knowledge of reaction rates and their parameter values. For biochemical reaction networks, these are often very difficult to obtain. An alternative is the computation of *steady-state fluxes* $\mathbf{v}^*$, which only requires solving the system of homogeneous linear equations

$$\mathbf{0} = \mathbf{N} \cdot \mathbf{v} . \quad (2)$$

Lower and upper bounds v_i^l, v_i^u for each flux v_i can be given such that $v_i^l \leq v_i \leq v_i^u$; an example is an irreversible reaction R_i which implies $v_i^l = 0$. The set of all feasible solutions then forms a pointed, convex, polyhedral *flux cone* in $\mathbb{R}^r$. The rays spanning the flux cone correspond to *elementary flux modes (EFMs)* or *extreme pathways (EPs)*, minimal subnetworks that are already balanced. Each feasible steady-state flux can be written as a nonnegative combination

$$\mathbf{v}^* = \sum_i \lambda_i \cdot \mathbf{e}_i, \quad \lambda_i \geq 0$$

of EFMs $\mathbf{e}_1, \mathbf{e}_2, \dots$, where the λ_i are the corresponding weights.

Even if in steady state, living cells grow and divide. Growth of a cell is often described by

a combination of fluxes $\mathbf{b}^T \cdot \mathbf{v}$, the total production rate of relevant metabolites to form new biomass. The *biomass function* given by $\mathbf{b} \in \mathbb{R}^r$ is determined experimentally. The technique of *flux balance analysis (FBA)* then solves the linear program

$$\max_{\mathbf{v}} \mathbf{b}^T \cdot \mathbf{v}$$

subject to

$$\mathbf{0} = \mathbf{N} \cdot \mathbf{v}$$

$$v_i^l \leq v_i \leq v_i^u$$

to yield a feasible flux vector that balances the network while maximizing growth. Alternative objective functions have been proposed, for instance, for higher organisms that do not necessarily maximize the growth of each cell.

Quasi-Steady-State Analysis

In many reaction mechanisms, a *quasi-steady-state assumption (QSSA)* can be made, postulating that the concentration of some of the involved species does not change. This assumption is often justified if reaction rates differ hugely, leading to a time scale separation, or if some concentrations are very high, such that their change is negligible for the mechanism. A typical example is the derivation of *Michaelis-Menten kinetics*, which corresponds to our example network. There, we may assume that the concentration of the intermediate species $E \cdot S$ stays approximately constant on the time scale of the overall conversion of substrate into product and that the substrate, at least initially, is in much larger abundance than the enzyme. On the slower time scale, this leads to the *Michaelis-Menten rate law*:

$$v_P = \frac{d}{dt}x_P(t) = \frac{v_{\max} \cdot x_S(t)}{K_m + x_S(t)} ,$$

with a maximal rate $v_{\max} = k_3 \cdot x_E^{\text{tot}}$, where x_E^{tot} is the total amount of enzyme and the Michaelis-Menten constant $K_m = (k_2 + k_3)/k_1$ as a direct relation between substrate concentration and production rate. This approximation reduces the number of states by two. Both parameters of

the Michaelis-Menten rate law are also better suited for experimental determination: $v_{\max}$ is the highest rate achievable and K_m corresponds to the substrate concentration that yields a rate of $v_{\max}/2$.

Cooperativity and Ultra-sensitivity

In the Michaelis-Menten mechanism, the production rate gradually increases with increasing substrate concentration, until saturation (Fig. 1; $h = 1$). A different behavior is achieved if the enzyme has several binding sites for the substrate and these sites interact such that occupation of one site alters the affinity of the other sites positively or negatively, phenomena known as positive and negative cooperativity, respectively. With QSSA arguments as before, the fraction of enzymes completely occupied by substrate molecules at time t is given by

$$v = \frac{v_{\max} \cdot x_S(t)}{K^h + x_S^h(t)}$$

where $K > 0$ is a constant and $h > 0$ is the *Hill coefficient*. The Hill coefficient determines the shape of the response with increasing substrate concentration: a coefficient of $h > 1$ ($h < 1$) indicates positive (negative) cooperativity; $h = 1$ reduces to the Michaelis-Menten mechanism. With increasing coefficient h , the response changes from gradual to switch-like, such that the transition from low to high response becomes more rapid as indicated in Fig. 1. This phenomenon is also known as *ultra-sensitivity*.

Constrained Dynamics

Due to the particular structure of the system equation (1), the trajectories $\mathbf{x}(t)$ of the network with $\mathbf{x}_0 = \mathbf{x}(0)$ are confined to the *stoichiometric subspace*, the intersection of $\mathbf{x}_0 + \text{Im}\mathbf{N}$ with the positive orthant. *Conservation relations* that describe conservation of mass are thus found as solutions to

$$\mathbf{c}^T \cdot \mathbf{N} = \mathbf{0},$$

and two initial conditions $\mathbf{x}_0, \mathbf{x}'_0$ lead to the same stoichiometric subspace if $\mathbf{c}^T \cdot \mathbf{x}_0 = \mathbf{c}^T \cdot \mathbf{x}'_0$. This allows for the analysis of, for example, bistability using only the reaction network structure.

Summary and Future Directions

Reactions networks, even in simple cells, typically encompass thousands of components and reactions, resulting in potentially high-dimensional nonlinear dynamic systems. In contrast to engineered systems, biology is characterized by a high degree of uncertainty of both model structure and parameter values. Therefore, system identification is a central problem in this domain. Specifically, advanced methods for model topology and parameter identification as well as for uncertainty quantification need to be developed that take into account the very limited observability of biological systems. In addition, biological systems operate on multiple time, length, and concentration scales. For example, genetic regulation usually operates on the time scale of minutes and involves very few molecules, whereas metabolism is significantly faster and states are well approximated by species

Deterministic Description of Biochemical Networks,

Fig. 1 Responses for cooperative enzyme reaction with Hill coefficient $h = 1, 3, 10$, respectively. All other parameters are set to 1

concentrations. Corresponding systematic frameworks for multiscale modeling, however, are currently lacking.

Diagnosis of Discrete Event Systems

Stéphane Lafortune
Department of Electrical Engineering and
Computer Science, University of Michigan, Ann
Arbor, MI, USA

Abstract

We discuss the problem of event diagnosis in partially observed discrete event systems. The objective is to infer the past occurrence, if any,

of an unobservable event of interest based on the observed system behavior and the complete model of the system. Event diagnosis is performed by diagnosers that are synthesized from the system model and that observe the system behavior at run-time. Diagnosability analysis is the off-line task of determining which events of interest can be diagnosed at run-time by diagnosers.

Keywords

Diagnosability · Diagnoser · Fault diagnosis · Verifier

Introduction

In this entry, we consider discrete event systems that are partially observable and discuss the two related problems of event diagnosis and diagnosability analysis. Let the DES of interest be denoted by M with event set E . Since M is partially observable, its set of events E is the disjoint union of a set of *observable events*, denoted by E_o , with a set of *unobservable events*, denoted by E_{uo} : $E = E_o \cup E_{uo}$. At this point, we do not specify how M is represented; it could be an automaton or a Petri net. Let L_M be the set of all strings of events in E that the DES M can execute, i.e., the (untimed) language model of the system; cf. the related entries, ► [Models for Discrete Event Systems: An Overview](#), ► [Supervisory Control of Discrete-Event Systems](#), and ► [Modeling, Analysis, and Control with Petri Nets](#). The set E_{uo} captures the fact that the set of sensors attached to the DES M is limited and may not cover all the events of the system. Unobservable events can be internal system events that are not directly “seen” by the monitoring agent that observes the behavior of M for diagnosis purposes. They can also be fault events that are included in the system model but are not directly observable by a dedicated sensor. For the purpose of diagnosis, let us designate a specific unobservable event of interest and denote it by $d \in E_{uo}$. Event d could be a fault event or some other significant event that is unobservable.

Before we can state the problem of event diagnosis, we need to introduce some notation. E^* is the set of all strings of any length $n \in \mathbb{N}$ that can be formed by concatenating elements of E . The unique string of length $n = 0$ is denoted by ε and is the identity element of concatenation. As in article ► [Supervisory Control of Discrete-Event Systems](#), section “Supervisory Control Under Partial Observations,” we define the projection function $P : E^* \rightarrow E_o^*$ that “erases” the unobservable events in a string and replaces them by ε . The function P is naturally extended to a set of strings by applying it to each string in the set, resulting in a set of projected strings. The observed behavior of M is the language $P(L_M)$ over event set E_o .

The problem of *event diagnosis*, or simply *diagnosis*, is stated as follows: how to infer the past occurrence of event d when observing strings in $P(L_M)$ at run-time, i.e., during the operation of the system? This is model-based inferencing, i.e., the monitoring agent knows L_M and the partition $E = E_o \cup E_{uo}$, and it observes strings in $P(L_M)$. When there are multiple events of interest, d_1 to d_n , and these events are *fault* events, we have a problem of *fault diagnosis*. In this case, the objective is not only to determine that a fault has occurred (commonly referred to as “fault detection”) but also to identify which fault has occurred, namely, which event d_i (commonly referred to as “fault isolation and identification”). Fault diagnosis requires that L_M contains not only the nominal or fault-free behavior of the system but also its behavior after the occurrence of each fault event d_i of interest, i.e., its faulty behavior. Event d_i is typically a fault of a component that leads to degraded behavior on the part of the system. It is not a catastrophic failure that would cause the system to completely stop operating, as such a failure would be immediately observable. The decision on which fault events d_i , along with their associated faulty behaviors, to include in the complete model L_M is a design one that is based on practical considerations related to the diagnosis objectives.

A complementary problem to event diagnosis is that of *diagnosability analysis*. Diagnosability

analysis is the off-line task of determining, on the basis of L_M and of E_o and E_{uo} , if any and all occurrences of the given event of interest d will eventually be diagnosed by the monitoring agent that observes the system behavior.

Event diagnosis and diagnosability analysis arise in numerous applications of systems that are modeled as DES. We mention a few application areas where DES diagnosis theory has been employed. In heating, ventilation, and air-conditioning systems, components such as valves, pumps, and controllers can fail in degraded modes of operation, such as a valve gets stuck open or stuck closed or a pump or controller gets stuck on or stuck off. The available sensors may not directly observe these faults, as the sensing abilities are limited. Fault diagnosis techniques are essential, since the components of the system are often not easily accessible. In monitoring communication networks, faults of certain transmitters or receivers are not directly observable and must be inferred from the set of successful communications and the topology of the network. In document processing systems, faults of internal components can lead to jams in the paper path or a decrease in image quality, and while the paper jam or the image quality is itself observable, the underlying fault may not be as the number of internal sensors is limited.

Without loss of generality, we consider a single event of interest to diagnose, d . When there are multiple events to diagnose, the methodologies that we describe in the remaining of this entry can be applied to each event of interest d_i , $i = 1, \dots, n$, individually; in this case, the other events of interest d_j , $j \neq i$ are treated the same as the other unobservable events in the set E_{uo} in the process of model-based inferencing.

Problem Formulation

Event Diagnosis

We start with a general language-based formulation of the event diagnosis problem. The information available to the agent that monitors the system behavior and performs the task of event diagnosis is the language L_M and the set of

observable events E_o , along with the specific string $t \in P(L_M)$ that it observes at run-time. The actual string generated by the system is $s \in L_M$ where $P(s) = t$. However, as far as the monitoring agent is concerned, the actual string that has occurred could be any string in $P^{-1}(t) \cap L_M$, where P^{-1} is the inverse projection operation, i.e., $P^{-1}(t)$ is the set of all strings $s_t \in E^*$ such that $P(s_t) = t$. Let us denote this estimate set by $\mathcal{E}(t) = P^{-1}(t) \cap L_M$, where “ $\mathcal{E}$ ” stands for “estimate.” If a string $s \in L_M$ contains event d , we write that $d \in L_M$; otherwise, we write that $d \notin L_M$.

The event diagnosis problem is to synthesize a diagnostic engine that will automatically provide the following answers from the observed t and from the knowledge of L_M and E_o :

1. **Yes**, if and only if $d \in s$ for all $s \in \mathcal{E}(t)$.
2. **No**, if and only if $d \notin s$ for all $s \in \mathcal{E}(t)$.
3. **Maybe**, if and only if there exists $s_Y, s_N \in \mathcal{E}(t)$ such that $d \in s_Y$ and $d \notin s_N$.

As defined, $\mathcal{E}(t)$ is a string-based estimate. In section “[Diagnosis of Automata](#),” we discuss how to build a finite-state structure that will encode the desired answers for the above three cases when the DES M is modeled by a deterministic finite-state automaton. The resulting structure is called a *diagnoser automaton*.

Diagnosability Analysis

Diagnosability analysis consists in determining, a priori, if any and all occurrences of event d in L_M will eventually be diagnosed, in the sense that if event d occurs, then the diagnostic engine is guaranteed to eventually issue the decision “Yes.” For the sake of technical simplicity, we assume hereafter that L_M is a *live* language, i.e., any trace in L_M can always be extended by one more event. In this context, we would not want the diagnostic engine to issue the decision “Maybe” for an arbitrarily long number of event occurrences after event d occurs. When this outcome is possible, we say that event d is *not diagnosable* in language L_M .

The property of *diagnosability* of DES is defined as follows. In view of the liveness

assumption on language L_M , any string s'_Y that contains event d can always be extended to a longer string, meaning that it can be made “arbitrarily long” after the occurrence of d . That is, for any s'_Y in L_M and for any $n \in \mathbb{N}$, there exists $s_Y = s'_Y t \in L_M$ where the length of t is equal to n . Event d is *not* diagnosable in language L_M if there exists such a string s_Y together with a second string s_N that does not contain event d , and such that $P(s_Y) = P(s_N)$. This means that the monitoring agent is unable to distinguish between s_Y and s_N , yet, the number of events after an occurrence of d can be made arbitrarily large in s_Y , thereby preventing diagnosis of event d within a finite number of events after its occurrence. On the other hand, if no such pair of strings (s_Y, s_N) exists in L_M , then event d is diagnosable in L_M . (The mathematically precise definition of diagnosability is available in the literature cited at the end of this entry.)

Diagnosis of Automata

We recall the definition of a deterministic finite-state automaton, or simply automaton, from article ► [Models for Discrete Event Systems: An Overview](#), with the addition of a set of unobservable events as in section “Supervisory Control Under Partial Observations” in article ► [Supervisory Control of Discrete-Event Systems](#). The automaton, denoted by G , is a four-tuple $G = (X, E, f, x_0)$ where X is the finite set of states, E is the finite set of events partitioned into $E = E_o \cup E_{uo}$, x_0 is the initial state, and f is the deterministic partial transition function $f : X \times E \rightarrow X$ that is immediately extended to strings $f : X \times E^* \rightarrow X$. For a DES M represented by an automaton G , L_M is the language generated by automaton G , denoted by $L(G)$ and formally defined as the set of all strings for which the extended f is defined. It is an infinite set if the transition graph of G has one or more cycles. In view of the liveness assumption made on L_M in the preceding section, G has no reachable deadlocked state, i.e., for all $s \in E^*$ such that $f(x, s)$ is defined, then there exists $\sigma \in E$ such that $f(x, s\sigma)$ is also defined.

To synthesize a diagnoser automaton that correctly performs the diagnostic task formulated in the preceding section, we proceed as follows. First, we perform the parallel composition (denoted by $\parallel$) of G with the two-state *label automaton* A_{label} that is defined as follows. $A_{\text{label}} = (\{N, Y\}, \{d\}, f_{\text{label}}, N)$, where f_{label} has two transitions defined: (i) $f_{\text{label}}(N, d) = Y$ and (ii) $f_{\text{label}}(Y, d) = Y$. The purpose of A_{label} is to record the occurrence of event d , which causes a transition to state Y . By forming $G^{\text{labeled}} = G \parallel A_{\text{label}}$, we record in the states of G^{labeled} , which are of the form (x_G, x_A) , if the first element of the pair, state $x_G \in X$, was reached or not by executing event d at some point in the past: if d was executed, then $x_A = Y$, otherwise $x_A = N$. (We refer the reader to Chap. 2 in Cassandras and Lafortune (2008) for the formal definition of parallel composition of automata.) By construction, $L(G^{\text{labeled}}) = L(G)$.

The second step of the construction of the diagnoser automaton is to build the *observer* of G^{labeled} , denoted by $\text{Obs}(G^{\text{labeled}})$, with respect to the set of observable events E_o . (We refer the reader to Chap. 2 in Cassandras and Lafortune (2008) for the definition of the observer automaton and for its construction.) The construction of the observer involves the standard subset construction algorithm for nondeterministic automata in automata theory; here, the unobservable events are the source of nondeterminism, since they effectively correspond to ε -transitions. The diagnoser automaton of G with respect to E_o is defined as $\text{Diag}(G) = \text{Obs}(G \parallel A_{\text{label}})$. Its event set is E_o .

The states of $\text{Diag}(G)$ are *sets* of state pairs of the form (x_G, x_A) where x_A is either N or Y . Examination of the state of $\text{Diag}(G)$ reached by string $t \in P[L(G)]$ provides the answers to the event diagnosis problem. Let us denote that state by x_{Diag}^t . Then:

1. The diagnostic decision is **Yes** if *all* state pairs in x_{Diag}^t have their second component equal to Y ; we call such a state a “Yes-state” of $\text{Diag}(G)$.
2. The diagnostic decision is **No** if *all* state pairs in x_{Diag}^t have their second component equal

to N ; we call such a state a “No-state” of $\text{Diag}(G)$.

3. The diagnostic decision is **Maybe** if there is at least one state pair in x_{Diag}^t whose second component is equal to Y and at least one state pair in x_{Diag}^t whose second component is equal to N ; we call such a state a “Maybe-state” of $\text{Diag}(G)$.

To perform run-time diagnosis, it therefore suffices to examine the current state of $\text{Diag}(G)$. Note that $\text{Diag}(G)$ can be computed off-line from G and stored in memory, so that run-time diagnosis requires only updating the new state of $\text{Diag}(G)$ on the basis of the most recent observed event (which is necessarily in E_o). If storing the entire structure of $\text{Diag}(G)$ is impractical, its current state can be computed on-the-fly on the basis of the most recent observed event and of the transition structure of G^{labeled} ; this involves one step of the subset construction algorithm.

As a simple example, consider the automaton G_1 shown in Fig. 1, where $E_{uo} = \{d\}$. The occurrence of event d changes the behavior of the system such that event c does not cause a return to the initial state 1 (identified by incoming arrow); instead, the system gets stuck in state 3 after d occurs.

Diagnosis of Discrete Event Systems, Fig. 1
Automaton G_1

Its diagnoser is depicted in Fig. 2. It contains one Yes-state, state $\{(3, Y)\}$ (abbreviated as “3Y” in the figure), one No-state, and two Maybe-states (similarly abbreviated). Two consecutive occurrences of event c , or an occurrence of b right after c , both indicate that the system must be in state 3, i.e., that event d must have occurred; this is captured by the two transitions from Maybe-state $\{(1, N), (3, Y)\}$ to the Yes-state in $\text{Diag}(G_1)$. As a second example, consider the automaton G_2 shown in Fig. 3, where the self-loop b at state 3

Diagnosis of Discrete Event Systems, Fig. 2
Diagnoser automaton of G_1

Diagnosis of Discrete Event Systems, Fig. 3
Automaton G_2

Diagnosis of Discrete Event Systems, Fig. 4
Diagnoser automaton of G_2

in G_1 has been removed. Its diagnoser is shown in Fig. 4.

Diagnoser automata provide as much information as can be inferred, from the available observations and the automaton model of the system, regarding the past occurrence of unobservable event d . However, we may want to answer the question: Can the occurrence of event d always be diagnosed? This is the realm of diagnosability analysis discussed in the next section.

Diagnosability Analysis of Automata

As mentioned earlier, diagnosability analysis consists in determining, a priori, if any and all occurrences of event d in L_M will eventually be diagnosed. In the case of diagnoser automata, we do not want $\text{Diag}(G)$ to loop forever in a cycle of Maybe-states and never enter a Yes-state if event d has occurred, as happens in the diagnoser in Fig. 2 for the string adb^n when n gets arbitrarily large. In this case, $\text{Diag}(G_1)$ loops in Maybe-state $\{(2, N), (3, Y)\}$, and the occurrence of d goes undetected. This shows that event d is not diagnosable in G_1 ; the counterexample is provided by strings $s_Y = adb^n$ and $s_N = ab^n$.

For systems modeled as automata, diagnosability can be tested with quadratic time com-

plexity in the size of the state space of G by forming a so-called twin-automaton (also called “verifier”) where G is parallel composed with itself, but synchronization is only enforced on *observable* events, allowing arbitrary interleavings of unobservable events. The test for diagnosability reduces to detection of cycles that occur after event d in the twin-automaton. It can be verified that for automaton G_2 in our example, event d is diagnosable. Indeed, it is clear from the structure of G_2 that $\text{Diag}(G_2)$ in Fig. 4 will never loop in Maybe-state $\{(2, N), (3, Y)\}$ if event d occurs; rather, after d occurs, G_2 can only execute c events, and after two such events, $\text{Diag}(G_2)$ enters Yes-state $\{(3, Y)\}$.

Note that diagnosability will not hold in an automaton that contains a cycle of unobservable events after the occurrence of event d , although this is not the only instance where the property is violated, as we saw in our simple example.

Diagnosis and Diagnosability Analysis of Petri Nets

There are several approaches for diagnosis and diagnosability analysis of DES modeled by Petri nets, depending on the boundedness properties of the net and on what is observable about its behavior. Let N be the Petri net model of the system, which consists of a Petri net structure along with an initial marking of all places. If the transitions of N are labeled by events in a set E , some by observable events in E_o and some by unobservable events in E_{uo} , and if the contents of the Petri net places are not observed except for the initial marking of N , then we have a language-based diagnosis problem as considered so far in this entry, for language $L(N)$ and for $E = E_o \cup E_{uo}$, with event of interest $d \in E_{uo}$. In this case, if the set of reachable states of the net is bounded, then we can use the reachability graph as an equivalent automaton model of the same system and build a diagnoser automaton as described earlier. It is also possible to encode diagnoser states into the original structure of net N by keeping track of all possible net markings following the observation of an event in E_o , appending the appropriate label (“N” or “Y”)

to each marking in the state estimate. This is reminiscent of the on-the-fly construction of the current state of the diagnoser automaton discussed earlier, except that the possible system states are directly listed as Petri net markings on the structure of N . Regarding diagnosability analysis, it can be performed using the twin-automaton technique of the preceding section, from the reachability graph of N .

Another approach that is actively being pursued in current literature is to exploit the structure of the net model N for diagnosis and for diagnosability analysis, instead of working with the automaton model obtained from its reachability graph. In addition to potential computational gains from avoiding the explicit generation of the entire set of reachable states, this approach is motivated by the need to handle Petri nets whose sets of reachable states are infinite and in particular Petri nets that generate languages that are not regular and hence cannot be represented by finite-state automata. Moreover, in this approach, one can incorporate potential observability of token contents in the places of the Petri nets. We refer the interested reader to the relevant chapters in Campos et al. (2013) and Seatzu et al. (2013) for coverage of these topics.

Current and Future Directions

The basic methodologies described so far for diagnosis and diagnosability analysis have been extended in many different directions. We briefly discuss a few of these directions, which are active research areas. Detailed coverage of these topics is beyond the scope of this entry and is available in the references listed at the end.

Diagnosis of *timed models* of DES has been considered, for classes of timed automata and timed Petri nets, where the objective is to ensure that each occurrence of event d is detected within a bounded time delay. Diagnosis of *stochastic models* of DES has been considered, in particular stochastic automata, where the hard diagnosability constraints are relaxed and detection of each occurrence of event d must be guaranteed with some probability $1 - \epsilon$, for some small $\epsilon > 0$. Stochastic models also allow handling of

unreliable sensors or noisy environments where event observations may be corrupted with some probability, such as when an occurrence of event a is observed as event a 80 % of the time and as some other event a' 20 % of the time.

Decentralized diagnosis is concerned with DES that are observed by several monitoring agents $i = 1, \dots, n$, each with its own set of observable events $E_{o,i}$ and each having access to the entire set of system behaviors, L_M . The task is to design a set of individual diagnosers, one for each set $E_{o,i}$, such that the n diagnosers together diagnose all the occurrences of event d . In other words, for each occurrence of event d in any string of L_M , there exists at least one diagnoser that will detect it (i.e., answer “Yes”). The individual diagnosers may or may not communicate with each other at run-time or they may communicate with a coordinating diagnoser that will fuse their information; several decentralized diagnosis architectures have been studied and their properties characterized. The focus in these works is the decentralized nature of the information available about the strings in L_M , as captured by the individual observable event sets $E_{o,i}$, $i = 1, \dots, n$.

Distributed diagnosis is closely related to decentralized diagnosis, except that it normally refers to situations where each individual diagnoser uses only part of the entire system model. Let M be an automaton G obtained by parallel composition of subsystem models: $G = \parallel_{i=1,n} G_i$. In distributed diagnosis, one would want to design each individual diagnoser Diag_i on the basis of G_i alone or on the basis of G_i and of an *abstraction* of the rest of the system, $\parallel_{j=1,n; j \neq i} G_j$. Here, the emphasis is on the distributed nature of the system, as captured by the parallel composition operation. In the case where M is a Petri net N , the distributed nature of the system may be captured by individual net models N_i , $i = 1, \dots, n$, that are coupled by common places, i.e., *place-bordered* Petri nets.

Robust diagnosis generally refers to decentralized or distributed diagnosis, but where one or more of the individual diagnosers may fail. Thus, there must be built-in redundancy in the set of individual diagnosers so that they together may still detect every occurrence of event d even if one or more of them ceases to operate.

So far we have considered a fixed and static set of observable events, $E_o \subset E$, where every occurrence of each event in E_o is always observed by the monitoring agent. However, there are many instances where one would want the monitoring agent to dynamically activate or deactivate the observability properties of a subset of the events in E_o ; this arises in situations where event monitoring is “costly” in terms of energy, bandwidth, or security reasons. This is referred to as the case of *dynamic observations*, and the goal is to synthesize sensor activation policies that minimize a given cost function while preserving the diagnosability properties of the system.

Recommended Reading

There is a very large amount of literature on diagnosis and diagnosability analysis of DES that has been published in control engineering, computer science, and artificial intelligence journals and conference proceedings. We mention a few recent books or survey articles that are a good starting point for readers interested in learning more about this active area of research. In the DES literature, the study of fault diagnosis and the formalization of diagnosability properties started in Lin (1994) and Sampath et al. (1995). Chapter 2 of the textbook Cassandras and Lafortune (2008) contains basic results about diagnoser automata and diagnosability analysis of DES, following the approach introduced in Sampath et al. (1995). The research monograph Lamperti and Zanella (2003) presents DES diagnostic methodologies developed in the artificial intelligence literature. The survey paper Zaytoon and Lafortune (2013) presents a detailed

overview of fault diagnosis research in the control engineering literature. The two edited books Campos et al. (2013) and Seatzu et al. (2013) contain chapters specifically devoted to diagnosis of automata and Petri nets, with an emphasis on automated manufacturing applications for the latter. Specifically, Chaps. 5, 14, 15, 17, and 19 in Campos et al. (2013) and Chaps. 22–25 in Seatzu et al. (2013) are recommended for further reading on several aspects of DES diagnosis. Zaytoon and Lafortune (2013) and the cited chapters in Campos et al. (2013) and Seatzu et al. (2013) contain extensive bibliographies.

Differential Geometric Methods in Nonlinear Control

Arthur J. Krener
Department of Applied Mathematics, Naval
Postgraduate School, Monterey, CA, USA

Abstract

In the early 1970s, concepts from differential geometry were introduced to study nonlinear

control systems. The leading researchers in this effort were Roger Brockett, Robert Hermann, Henry Hermes, Alberto Isidori, Velimir Jurdjevic, Arthur Krener, Claude Lobry, and Hector Sussmann. These concepts revolutionized our knowledge of the analytic properties of control systems, e.g., controllability, observability, minimality, and decoupling. With these concepts, a theory of nonlinear control systems emerged that generalized the linear theory. This theory of nonlinear systems is largely parallel to the linear theory, but of course it is considerably more complicated.

Codistribution · Distribution · Frobenius theorem · Involutive distribution · Lie jet

Introduction

This is a brief survey of the influence of differential geometric concepts on the development of nonlinear systems theory. Section “[A Primer on Differential Geometry](#)” reviews some concepts and theorems of differential geometry. Nonlinear controllability and nonlinear observability are discussed in sections “[Controllability of Nonlinear Systems](#)” and “[Observability for Nonlinear Systems](#)”. Section “[Minimal Realizations](#)” discusses minimal realizations of nonlinear systems, and section “[Disturbance Decoupling](#)” discusses the disturbance decoupling problem.

A Primer on Differential Geometry

Perhaps a better title might be “A Primer on Differential Topology” since we will not treat Riemannian or other metrics. A n -dimensional manifold $\mathcal{M}$ is a topological space that is locally homeomorphic to a subset of $\mathbb{R}^n$. For simplicity, we shall restrict our attention to smooth (C^∞) manifolds and smooth objects on them. Around each point $p \in \mathcal{M}$, there is at least one coordinate chart that is a neighborhood $\mathcal{N}_p \subset \mathcal{M}$ and a

homeomorphism $x : \mathcal{N}_p \rightarrow \mathcal{U}$ where $\mathcal{U}$ is an open subset of $\mathbb{R}^n$. When two coordinate charts overlap, the change of coordinates should be smooth. For simplicity, we restrict our attention to differential geometric objects described in local coordinates.

In local coordinates, a vector field is just an ODE of the form

$$\dot{x} = f(x) \quad (1)$$

where $f(x)$ is a smooth $\mathbb{R}^{n \times 1}$ valued function of x . In a different coordinate chart with local coordinates z , this vector field would be represented by a different formula:

$$\dot{z} = g(z)$$

If the charts overlap, then on the overlap they are related:

$$f(x(z)) = \frac{\partial x}{\partial z}(z)g(z), \quad g(z(x)) = \frac{\partial z}{\partial x}(x)f(x)$$

Since $f(x)$ is smooth, it generates a smooth flow $\phi(t, x^0)$ where for each t , the mapping $x \mapsto \phi(t, x^0)$ is a local diffeomorphism and for each x^0 the mapping $t \mapsto \phi(t, x^0)$ is a solution of the ODE (1) satisfying the initial condition $\phi(0, x^0) = x^0$. We assume that all the flows are complete, i.e., defined for all $t \in \mathbb{R}$, $x \in \mathcal{M}$. The flows are one parameter groups, i.e., $\phi(t, \phi(s, x^0)) = \phi(t+s, x^0) = \phi(s, \phi(t, x^0))$.

If $f(x^0) = b$, a constant vector, then locally the flow looks like translation, $\phi(t, x^1) = x^1 + tb$. If $f(x^0) \neq 0$, then we can always choose local coordinates z so that in these coordinates the vector field is constant. Without loss of generality, we can assume that $x^0 = 0$ and that the first component of f is $f_1(0) \neq 0$. Define the local change of coordinates: $x(z) = \phi(z_1, x^1(z))$ where $x^1(z) = (0, z_2, \dots, z_n)'$. It is not hard to see that this is a local diffeomorphism and that, in z coordinates, the vector field is the first unit vector.

If $f(x^0) = 0$ let $F = \frac{\partial f}{\partial x}(x^0)$, then if all the eigenvalues of F are off the imaginary axis, then the integral curves of $f(x)$ and

$$\dot{z} = Fz \quad (2)$$

are locally topologically equivalent (Arnol'd 1983). This is the Grobman-Hartman theorem. There exists a local homeomorphism $z = h(x)$ that carries $x(t)$ trajectories into $z(s)$ trajectories in some neighborhood of $x^0 = 0$. This homeomorphism need not preserve time $t \neq s$, but it does preserve the direction of time. Whether these flows are locally diffeomorphic is a more difficult question that was explored by Poincaré. See the section on feedback linearization (Krener 2013).

If all the eigenvalues of F are in the open left half plane, then the linear dynamics (2) is globally asymptotically stable around $z^0 = 0$, i.e., if the flow of (2) is $\psi(t, z)$, then $\psi(t, z^1) \rightarrow 0$ as $t \rightarrow \infty$. Then it can be shown that the nonlinear dynamics is locally asymptotically stable, $\phi(t, x^1) \rightarrow x^0$ as $t \rightarrow \infty$ for all x^1 in some neighborhood of x^0 .

One forms, $\omega(x)$, are dual to vector fields. The simplest example of a one form (also called a covector field) is the differential $dh(x)$ of a scalar-valued smooth function $h(x)$. This is the $\mathbb{R}^{1 \times n}$ covector field

$$\omega(x) = \left[\frac{\partial h}{\partial x_1}(x) \dots \frac{\partial h}{\partial x_n}(x) \right]$$

Sometimes this is written as

$$\omega(x) = \sum_1^n \frac{\partial h}{\partial x_i}(x) dx_i$$

The most general smooth one form is of the form

$$\begin{aligned} \omega(x) &= [\omega^1(x) \dots \omega^n(x)] \\ &= \sum_{i=1}^n \omega^i(x) dx_i \end{aligned}$$

where the $\omega^i(x)$ are smooth functions. The duality between one forms and vector fields is the bilinear pairing

$$\begin{aligned} \langle \omega(x), f(x) \rangle &= \omega(f)(x) = \omega(x)f(x) \\ &= \sum_{i=1}^n \omega^i(x) f_i(x) \end{aligned}$$

Just as a vector field can be thought of as a first-order ODE, a one form can be thought of as a first-order PDE. Given $\omega(x)$, find $h(x)$ such that $dh(x) = \omega(x)$. A one form $\omega(x)$ is said to be exact if there exists such an $h(x)$. Of course if there is one solution, then there are many all differing by a constant of integration which we can take as the value of h at some point x^0 .

Unlike smooth first-order ODEs, smooth first-order PDEs do not always have a solution. There are integrability conditions and topological conditions that must be satisfied. Suppose $dh(x) = \omega(x)$, then $\frac{\partial h}{\partial x_i}(x) = \omega^i(x)$ so

$$\frac{\partial \omega^i}{\partial x_j}(x) = \frac{\partial^2 h}{\partial x_j \partial x_i}(x) = \frac{\partial^2 h}{\partial x_i \partial x_j}(x) = \frac{\partial \omega^j}{\partial x_i}(x)$$

Therefore, for the PDE to have a solution, the integrability conditions

$$\frac{\partial \omega^i}{\partial x_j}(x) - \frac{\partial \omega^j}{\partial x_i}(x) = 0$$

must be satisfied. The exterior derivative of a one form is a skew-symmetric matrix field

$$d\omega(x) = \sum_{i < j} \left(\frac{\partial \omega^i}{\partial x_j}(x) - \frac{\partial \omega^j}{\partial x_i}(x) \right) dx_i \wedge dx_j$$

A one form $\omega(x)$ is said to be closed if $d\omega(x) = 0$. This is locally sufficient for there to exist an $h(x)$ such that $dh(x) = \omega(x)$.

Every exact form is closed but not every closed form is exact. A counter example on $\mathbb{R}^2$ is

$$\omega(x) = [-x_2 \ x_1]$$

This is closed but not exact. The line integral of this convector field around any circle centered at the origin is 2π . If it were exact, the line integral would have been zero because the curve ends where it begins.

The Lie derivative of a scalar-valued function $h(x)$ by a vector field $f(x)$ is denoted to be the scalar-valued function

$$L_f(h)(x) = \frac{\partial h}{\partial x}(x)f(x) = \langle dh(x), f(x) \rangle$$

This can be iterated

$$L_f^k(h)(x) = \frac{\partial L_f^{k-1}h}{\partial x}(x)f(x)$$

If $h(x) \in \mathbb{R}^{p \times 1}$, then $L_f(h)(x) \in \mathbb{R}^{p \times 1}$.

The Lie bracket of two vector fields $f^1(x)$ and $f^2(x)$ is another vector field

$$[f^1, f^2](x) = \frac{\partial f^2}{\partial x}(x)f^1(x) - \frac{\partial f^1}{\partial x}(x)f^2(x)$$

Clearly, the Lie bracket is skew symmetric, $[f^1, f^2](x) = -[f^2, f^1](x)$. It also satisfies the Jacobi identity

$$[f^1, [f^2, f^3]](x) + [f^2, [f^3, f^1]](x) + [f^3, [f^1, f^2]](x) = 0$$

Repeated Lie brackets are often expressed inductively as

$$ad_f^0(g)(x) = g(x)$$

$$ad_f^k(g)(x) = [f, ad_f^{k-1}(g)](x)$$

The geometric interpretation of the Lie bracket $[f, g](x)$ is the infinitesimal commutator of their flows $\phi(t, x)$ and $\psi(t, x)$, i.e.,

$$\psi(t, \phi(t, x)) - \phi(t, \psi(t, x)) = [f, g](x)t^2 + O(t)^3$$

Another interpretation of the Lie bracket is given by the Lie series expansion

$$g(\phi(t, x)) = \sum_{k=0}^{\infty} (-1)^k ad_f^k(g)(x) \frac{t^k}{k!}$$

This is a Taylor series expansion which is convergent for small $|t|$ if f, g are real analytic vector fields. Another Lie series is

$$h(\phi(t, x)) = \sum_{k=0}^{\infty} L_f^k(h)(x) \frac{t^k}{k!}$$

Given a smooth mapping $z = \theta(x)$ from an open subset of $\mathbb{R}^n$ to an open subset of $\mathbb{R}^m$ and vector fields $f(x)$ and $g(z)$ on these open subsets, we say $f(x)$ is θ -related to $g(z)$ if

$$g(\theta(x)) = \frac{\partial \theta}{\partial x}(x) f(x)$$

It is not hard to see that if $f^1(x), f^2(x)$ are θ -related to $g^1(z), g^2(z)$, then $[f^1, f^2](x)$ is θ -related to $[g^1, g^2](z)$. For this reason, we say that the Lie bracket is an intrinsic differentiation. The other intrinsic differentiation is the exterior derivative operation d .

The Lie derivative of a one form $\omega(x)$ by a vector field $f(x)$ is given by

$$L_f(\omega)(x) = \sum_{i,j} \left(\frac{\partial \omega^i}{\partial x_j}(x) f_j(x) + \omega_j(x) \frac{\partial f_j}{\partial x_i}(x) \right) dx_i$$

It is not hard to see that

$$L_f(\langle \omega, g \rangle)(x) = \langle L_f(\omega), g \rangle(x) + \langle \omega, [f, g] \rangle(x)$$

and

$$L_f(dh)(x) = d(L_f(h))(x) \quad (3)$$

Control systems involve multiple vector fields. A distribution $\mathcal{D}$ is a set of vector fields on $\mathcal{M}$ that is closed under addition of vector fields and under multiplication by scalar functions. A distribution defines at each $x \in \mathcal{M}$ a subspace of the tangent space

$$D(x) = \{f(x) : f \in \mathcal{D}\}$$

These subspaces form a subbundle D of the tangent bundle. If the subspaces are all of the same dimension, then the distribution is said to be nonsingular. We will restrict our attention to nonsingular distributions.

A codistribution (or Pfaffian system) $\mathcal{E}$ is a set of one forms on $\mathcal{M}$ that is closed under

addition and multiplication by scalar functions. A codistribution defines at each $x \in \mathcal{M}$ a subspace of the cotangent space

$$\{\omega(x) : \omega \in \mathcal{E}\}$$

These subspaces form a subbundle E of the cotangent bundle. If the subspaces are all of the same dimension, then the codistribution is said to be nonsingular. Again, we will restrict our attention to nonsingular codistributions.

Every distribution $\mathcal{D}$ defines a dual codistribution

$$\mathcal{D}^* = \{\omega(x) : \omega(x)f(x) = 0, \text{ for all } f(x) \in \mathcal{D}\}$$

and vice versa

$$\mathcal{E}_* = \{f(x) : \omega(x)f(x) = 0, \text{ for all } \omega(x) \in \mathcal{E}\}$$

A k dimensional distribution $\mathcal{D}$ (or its dual codistribution $\mathcal{D}^*$) can be thought of as a system of PDEs on $\mathcal{M}$. Find $n - k$ independent functions $h_1(x), \dots, h_{n-k}(x)$ such that

$$dh_i(x)f(x) = 0 \text{ for all } f(x) \in \mathcal{D}$$

The functions $h_1(x), \dots, h_{n-k}(x)$ are said to be independent if $dh_1(x), \dots, dh_{n-k}(x)$ are linearly independent at every $x \in \mathcal{M}$. In other words, $dh_1(x), \dots, dh_{n-k}(x)$ span $\mathcal{D}^*$ over the space of smooth functions.

The Frobenius theorem gives the integrability conditions for these functions to exist locally. The distribution $\mathcal{D}$ must be involutive, i.e., closed under the Lie bracket,

$$[\mathcal{D}, \mathcal{D}] = \{[f, g] : f, g \in \mathcal{D}\} \subset \mathcal{D}$$

When the functions exist, their joint level sets $\{x : h_i(x) = c_i, i = 1, \dots, n - k\}$ are the leaves of a local foliation. Through each x^0 in a convex local coordinate chart $\mathcal{N}$, there exists locally a k -dimensional submanifold $\{x \in \mathcal{N} : h_i(x) = h_i(x^0)\}$. At each x^1 in this submanifold, its tangent space is $D(x)$. Whether these $h_i(x)$ exist globally to define a global foliation, a partition of $\mathcal{M}$ into smooth submanifolds, is

a delicate question. Consider a distribution on $\mathbb{R}^2$ generated by a constant vector field $f(x) = b$ of irrational slope, b_2/b_1 is irrational. Construct the torus T^2 as the quotient of $\mathbb{R}^2$ by the integer lattice Z^2 . The distribution passes to the quotient and since it is one dimensional, it is clearly involutive. The leaves of the quotient distribution are curves that wind around the torus indefinitely, and each curve is dense in T^2 . Therefore, any smooth function $h(x)$ that is constant on such a leaf is constant on all of T^2 . Hence, the local foliation does not extend to a global foliation.

Another delicate question is whether the quotient space of $\mathcal{M}$ by a foliation induced by an involutive distribution is a smooth manifold (Sussmann 1975). This is always true locally, but it may not hold globally. Think of the foliation of T^2 discussed above.

Given $k \leq n$ vector fields $f^1(x), \dots, f^k(x)$ that are linearly independent at each x and that commute, $[f^i, f^j](x) = 0$, there exists a local change of coordinates $z = z(x)$ so that in the new coordinates the vector fields are the first k unit vectors.

The involutive closure $\bar{\mathcal{D}}$ of $\mathcal{D}$ is the smallest involutive distribution containing $\mathcal{D}$. As with all distributions, we always assume implicitly that is nonsingular. A point x^1 is $\mathcal{D}$ -accessible from x^0 if there exists a continuous and piecewise smooth curve joining x^0 to x^1 whose left and right tangent vectors are always in $\mathcal{D}$. Obviously $\mathcal{D}$ -accessibility is an equivalence relation. Chow's theorem (1939) asserts that its equivalence classes are the leaves of the foliation induced by $\bar{\mathcal{D}}$. Chow's theorem goes a step further. Suppose $f^1(x), \dots, f^k(x)$ span $\mathcal{D}(x)$ at each $x \in \mathcal{M}$ then given any two points x^0, x^1 in a leaf of $\bar{\mathcal{D}}$, there is a continuous and piecewise smooth curve joining x^0 to x^1 whose left and right tangent vectors are always one of the $f^i(x)$.

Controllability of Nonlinear Systems

An initialized nonlinear system that is affine in the control is of the form

$$\begin{aligned}\dot{x} &= f(x) + g(x)u \\ &= f(x) + \sum_{j=1}^m g^j(x)u_j \\ y &= h(x) \\ x(0) &= x^0\end{aligned}\quad (4)$$

where the state x are local coordinates on an n -dimensional manifold $\mathcal{M}$, the control u is restricted to lie in some set $\mathcal{U} \subset \mathbb{R}^m$, and the output y takes values $\mathbb{R}^p$. We shall only consider such systems.

A particular case is a linear system of the form

$$\begin{aligned}\dot{x} &= Fx + Gu \\ y &= Hx \\ x(0) &= x^0\end{aligned}\quad (5)$$

where $\mathcal{M} = \mathbb{R}^n$ and $\mathcal{U} = \mathbb{R}^m$.

The set $\mathcal{A}_t(x^0)$ of points accessible at time $t \geq 0$ from x^0 is the set of all $x^1 \in \mathcal{M}$ such that there exists a bounded, measurable control trajectory $u(s) \in \mathcal{U}$, $0 \leq s \leq t$, so that the solution of (4) satisfies $x(t) = x^1$. We define $\mathcal{A}(x^0)$ as the union of $\mathcal{A}_t(x^0)$ for all $t \geq 0$. The system (4) is said to be controllable at time $t > 0$ if $\mathcal{A}_t(x^0) = \mathcal{M}$ and controllable in forward time if $\mathcal{A}(x^0) = \mathcal{M}$.

For linear systems, controllability is a rather straightforward matter, but for nonlinear systems it is more subtle with numerous variations. The variation of constants formula gives the solution of the linear system (5) as

$$x(t) = e^{Ft}x^0 + \int_0^t e^{F(t-s)}Gu(s)ds$$

so $\mathcal{A}_t(x^0)$ is an affine subspace of $\mathbb{R}^n$ for any $t > 0$. It is not hard to see that the columns of

$$\begin{bmatrix} G & \dots & F^{n-1}G \end{bmatrix}\quad (6)$$

are tangent to this affine subspace, so if this matrix is of rank n , then $\mathcal{A}_t(x^0) = \mathbb{R}^n$ for any $t > 0$. This is the so-called controllability rank condition for linear systems.

Turning to the nonlinear system (4), let $\mathcal{D}$ be the distribution spanned by the vector fields $f(x), g^1(x), \dots, g^m(x)$, and let $\bar{\mathcal{D}}$ be its involutive closure. It is clear that $\mathcal{A}(x^0)$ is contained in

the leaf of $\bar{\mathcal{D}}$ through x^0 . Krener (1971) showed that $\mathcal{A}(x^0)$ has nonempty interior in this leaf. More precisely, $\mathcal{A}(x^0)$ is between an open set and its closure in the relative topology of the leaf.

Let $\mathcal{D}_0$ be the smallest distribution containing the vector fields $g^1(x), \dots, g^m(x)$ and invariant under bracketing by $f(x)$, i.e.,

$$[f, \mathcal{D}_0] \subset \mathcal{D}_0$$

and let $\bar{\mathcal{D}}_0$ be its involutive closure. Sussmann and Jurdjevic (1972) showed that $\mathcal{A}_t(x^0)$ is in the leaf of $\bar{\mathcal{D}}_0$ through x^0 , and it is between an open set and its closure in the topology of this leaf.

For linear systems (5) where $f(x) = Fx$ and $g^j(x) = G^j$, the j th column of G , it is not hard to see that

$$ad_f^k(g^j)(x) = (-1)^k F^k G^j$$

so the nonlinear generalization of the controllability rank condition is that at each x the dimension of $\bar{\mathcal{D}}_0(x)$ is n . This guarantees that $\mathcal{A}_t(x^0)$ is between an open set and its closure in the topology of $\mathcal{M}$.

The condition that

$$\text{dimension } \bar{\mathcal{D}}(x) = n \quad (7)$$

is referred to as the nonlinear controllability rank condition. This guarantees that $\mathcal{A}(x^0)$ is between an open set and its closure in the topology of $\mathcal{M}$.

There are stronger interpretations of controllability for nonlinear systems. One is short time local controllability (STLC). The definition of this is that the set of accessible points from x^0 in any small $t > 0$ with state trajectories restricted to an arbitrarily small neighborhood of x^0 should contain x^0 in its interior. Hermes (1994) and others have done work on this.

Observability for Nonlinear Systems

Two possible initial states x^0, x^1 for the nonlinear system are distinguishable if there exists a control $u(\cdot)$ such that the corresponding

outputs $y^0(t), y^1(t)$ are not equal. They are short time distinguishable if there is an $u(\cdot)$ such that $y^0(t) \neq y^1(t)$ for all small $t > 0$. They are locally short time distinguishable if in addition the corresponding state trajectories do not leave an arbitrarily small open set containing x^0, x^1 . The open set need not be connected. A nonlinear system is (short time, locally short time) observable if every pair of initial states is (short time, locally short time) distinguishable. Finally, a nonlinear system is (short time, locally short time) locally observable if every x^0 has a neighborhood such that every other point x^1 in the neighborhood is (short time, locally short time) distinguishable from x^0 .

For a linear system (5), all these definitions coalesce into a single concept of observability which can be checked by the observability rank condition which is that the rank of

$$\begin{bmatrix} H \\ HF \\ \vdots \\ HF^{n-1} \end{bmatrix} \quad (8)$$

equals n .

The corresponding concept for nonlinear systems involves $\mathcal{E}$, the smallest codistribution containing $dh_1(x), \dots, dh_p(x)$ that is invariant under repeated Lie differentiation by the vector fields $f(x), g^1(x), \dots, g^m(x)$. Let

$$E(x) = \{\omega(x) : \omega \in \mathcal{E}\}$$

The nonlinear observability rank condition is

$$\text{dimension } E(x) = n \quad (9)$$

for all $x \in \mathcal{M}$. This condition guarantees that the nonlinear system is locally short time, locally observable. It follows from (3) that $\mathcal{E}$ is spanned by a set of exact one form, so its dual distribution $\mathcal{E}^*$ is involutive.

For a linear system (5), the input–output mapping from $x(0) = x^i, i = 0, 1$ is

$$y^i(t) = He^{Ft}x^i + \int_0^t He^{F(t-s)}Gu(s)ds$$

The difference is

$$y1(t) - y^0(t) = He^{Ft}(x^1 - x^0)$$

So if one input $u(\cdot)$ distinguishes x^0 from x^1 , then so does every input.

For nonlinear systems, this is not necessarily true. That prompted Gauthier et al. (1992) to introduce a stronger concept of observability for nonlinear systems. For simplicity, we describe it for scalar input and scalar output systems. A nonlinear system is uniformly observable for any input if there exist local coordinates so that it is of the form

$$\begin{aligned} y &= x_1 + h(u) \\ \dot{x}_1 &= x_2 + f_1(x_1, u) \\ &\vdots \\ \dot{x}_{n-1} &= x_n + f_{n-1}(x_1, \dots, x_{n-2}, u) \\ \dot{x}_n &= f_n(x, u) \end{aligned}$$

Clearly if we know $u(\cdot)$, $y(\cdot)$, then by repeated differentiation of $y(\cdot)$, we can reconstruct $x(\cdot)$. It has been shown that for nonlinear systems that are uniformly observable for any input, the extended Kalman filter is a locally convergent observer (Krener 2002a), and the minimum energy estimator is globally convergent (Krener 2002b).

Minimal Realizations

The initialized nonlinear system (4) can be viewed as defining an input–output mapping from input trajectories $u(\cdot)$ to output trajectories $y(\cdot)$. Is it a minimal realization of this mapping, does there exist an initialized nonlinear system on a smaller dimensional state space that realizes the same input–output mapping?

Kalman showed that (5) initialized at $x^0 = 0$ is minimal iff the controllability rank condition

and the observability rank condition hold. He also showed how to reduce a linear system to a minimal one.

If the controllability rank condition does not hold, then the span of (6) dimension is $k < n$. This subspace contains the columns of G and is invariant under multiplication by F . In fact, it is the maximal subspace with these properties. So the linear system can be restricted to this k -dimensional subspace, and it realizes the same input–output mapping from $x^0 = 0$. The restricted system satisfies the controllability rank condition.

If the observability rank condition does not hold, then the kernel of (8) is a subspace of $\mathbb{R}^{n \times 1}$ of dimension $n - l > 0$. This subspace is in the kernel of H and is invariant under multiplication by F . In fact, it is the maximal subspace with these properties. Therefore, there is a quotient linear system on the $\mathbb{R}^{n \times 1}$ mod, the kernel of (8) which has the same input–output mapping. The quotient is of dimension $l < n$, and it realizes the same input–output mapping. The quotient system satisfies the observability rank condition.

By employing these two steps in either order, we pass to a minimal realization of the input–output map of (5) from $x^0 = 0$. Kalman also showed that two linear minimal realizations differ by a linear change of state coordinates.

An initialized nonlinear system is a realization of minimal dimension of its input–output mapping if the nonlinear controllability rank condition (7) and the nonlinear observability rank condition (9) hold.

If the nonlinear controllability rank condition (7) fails to hold because the dimension of $D(x)$ is $k < n$, then by replacing the state space $\mathcal{M}$ with the k dimensional leaf through x^0 of the foliation induced by $\mathcal{D}$, we obtain a smaller state space on which the nonlinear controllability rank condition (7) holds. The input–output mapping is unchanged by this restriction.

Suppose the nonlinear observability rank condition (9) fails to hold because the dimension of $E(x)$ is $l < n$. Then consider a convex neighborhood $\mathcal{N}$ of x^0 . The distribution $\mathcal{E}^*$ induces a local foliation of $\mathcal{N}$ into leaves of dimension $n - l > 0$. The nonlinear system leaves this

local foliation invariant in the following sense. Suppose x^0 and x^1 are on the same leaf then if $x^i(t)$ is the trajectory starting at x^i , then $x^0(t)$ and $x^1(t)$ are on the same leaf as long as the trajectories remain in $\mathcal{N}$. Furthermore, $h(x)$ is constant on leaves so $y^0(t) = y^1(t)$. Hence, there exists locally a nonlinear system whose state space is the leaf space. On this leaf space, the nonlinear observability rank condition holds (9), and the projected system has the same input–output map as the original locally around x^0 . If the leaf space of the foliation induced by $\mathcal{E}^*$ admits the structure of a manifold, then the reduced system can be defined globally on it. Sussmann (1973) and Sussmann (1977) studied minimal realizations of analytic nonlinear systems.

The state space of two minimal nonlinear systems need not be diffeomorphic. Consider the system

$$\dot{x} = u, \quad y = \sin x$$

where x, u are scalars. We can take the state space to be either $\mathcal{M} = \mathbb{R}$ or $\mathcal{M} = S^1$, and we will realize the same input–output mapping. These two state spaces are certainly not diffeomorphic but one is a covering space of the other.

Lie Jet and Approximations

Consider two initialized nonlinear controlled dynamics

$$\begin{aligned} \dot{x} &= f^0(x) + \sum_{j=1}^m f^j(x)u_j \\ x(0) &= x^0 \end{aligned} \quad (10)$$

$$\begin{aligned} \dot{z} &= g^0(z) + \sum_{j=1}^m g^j(z)u_j \\ z(0) &= z^0 \end{aligned} \quad (11)$$

Suppose that (10) satisfies the nonlinear controllability rank condition (7). Further, suppose that there is a smooth mapping $\Phi(x) = z$ and constants $M > 0, \epsilon > 0$ such that for any $\|u(t)\| < 1$, the corresponding trajectories $x(t)$ and $z(t)$ satisfy

$$\|\Phi(x(t)) - z(t)\| < Mt^{k+1} \quad (12)$$

for $0 \leq t < \epsilon$.

Then it is not hard to show that the linear map $L = \frac{\partial \Phi}{\partial x}(x^0)$ takes brackets up to order k of the vector fields f^j evaluated at x^0 into the corresponding brackets of the vector fields g^j evaluated at z^0 ,

$$\begin{aligned} L[f^{j_l}[\dots[f^{j_2}, f^{j_1}]\dots]](x^0) \\ = [g^{j_l}[\dots[g^{j_2}, g^{j_1}]\dots]](z^0) \end{aligned} \quad (13)$$

for $1 \leq l \leq k$.

On the other hand, if there is a linear map L such that (13) holds for $1 \leq l \leq k$, then there exists a smooth mapping $\Phi(x) = z$ and constants $M > 0, \epsilon > 0$ such that for any $\|u(t)\| < 1$, the corresponding trajectories $x(t)$ and $z(t)$ satisfy (12).

The k -Lie jet of (10) at x^0 is the tree of brackets $[f^{j_l}[\dots[f^{j_2}, f^{j_1}]\dots]](x^0)$ for $1 \leq l \leq k$. In some sense these are the coordinate-free Taylor series coefficients of (10) at x^0 .

The dynamics (10) is free-nilpotent of degree k if all these brackets are as linearly independent as possible consistent with skew symmetry and the Jacobi identity and all higher degree brackets are zero. If it is free to degree k , the controlled dynamics (10) can be used to approximate any other controlled dynamics (11) to degree k . Because it is nilpotent, integrating (10) reduces to repeated quadratures. If all brackets with two or more f^i , $1 \leq i \leq m$ are zero at x^0 , then (10) is linear in appropriate coordinates. If all brackets with three or more f^i , $1 \leq i \leq m$ are zero at x^0 , then (10) is quadratic in appropriate coordinates. The references Krener and Schaettler (1988) and Krener (2010a, b) discuss the structure of the reachable sets for such systems.

Disturbance Decoupling

Consider a control system affected by a disturbance input $w(t)$

$$\begin{aligned}\dot{x} &= f(x) + g(x)u + b(x)w \\ y &= h(x)\end{aligned}\quad (14)$$

The disturbance decoupling problem is to find a feedback $u = \kappa(x)$, so that in the closed-loop system, the output $y(t)$ is not affected by the disturbance $w(t)$. Wonham and Morse (1970) solved this problem for a linear system

$$\begin{aligned}\dot{x} &= Fx + Gu + Bw \\ y &= Hx\end{aligned}\quad (15)$$

To do so, they introduced the concept of an F, G invariant subspace. A subspace $\mathcal{V} \subset \mathbb{R}^n$ is F, G invariant if

$$F\mathcal{V} \subset \mathcal{V} + \mathcal{G} \quad (16)$$

where $\mathcal{G}$ is the span of the columns of G . It is easy to see that $\mathcal{V}$ is F, G invariant iff there exists a $K \in \mathbb{R}^{m \times n}$ such that

$$(F + GK)\mathcal{V} \subset \mathcal{V} \quad (17)$$

The feedback gain K is called a friend of $\mathcal{V}$.

It is easy from (16) that if $\mathcal{V}^i$ is F, G invariant for $i = 1, 2$, then $\mathcal{V}^1 + \mathcal{V}^2$ is also. So there exists a maximal F, G invariant subspace $\mathcal{V}^{\max}$ in the kernel of H . Wonham and Morse showed that the linear disturbance decoupling problem is solvable iff $\mathcal{B} \subset \mathcal{V}^{\max}$ where $\mathcal{B}$ is the span of the columns of B .

Isidori et al. (1981a) and independently Hirschorn (1981) solved the nonlinear disturbance decoupling problem. A distribution $\mathcal{D}$ is locally f, g invariant if

$$\begin{aligned}[f, \mathcal{D}] &\subset \mathcal{D} + \Gamma \\ [g^j, \mathcal{D}] &\subset \mathcal{D} + \Gamma\end{aligned}\quad (18)$$

for $j = 1, \dots, m$ where Γ is the distribution spanned by the columns of g . In Isidori et al. (1981b) it is shown that if $\mathcal{D}$ is locally f, g invariant, then so is its involutive closure.

A distribution $\mathcal{D}$ is f, g invariant if there exists $\alpha(x) \in \mathbb{R}^{m \times 1}$ and invertible $\beta(x) \in \mathbb{R}^{m \times m}$ such that

$$\begin{aligned}[f + g\alpha, \mathcal{D}] &\subset \mathcal{D} \\ \left[\sum_j g^j \beta_j^k, \mathcal{D}\right] &\subset \mathcal{D}\end{aligned}\quad (19)$$

for $k = 1, \dots, m$. It is not hard to see that a f, g invariant is locally f, g invariant. It is shown in Isidori et al. (1981b) that if $\mathcal{D}$ is a locally f, g invariant distribution, then locally there exists $\alpha(x)$ and $\beta(x)$ so that (19) holds. Furthermore, if the state space is simply connected, then $\alpha(x)$ and $\beta(x)$ exist globally, but the matrix field $\beta(x)$ may fail to be invertible at some x .

From (18), it is clear that if $\mathcal{D}^i$ is locally f, g invariant for $i = 1, 2$, then so is $\mathcal{D}^1 + \mathcal{D}^2$. Hence, there exists a maximal locally f, g invariant distribution $\mathcal{D}^{\max}$ in the kernel of dh . Moreover, this distribution is involutive. The disturbance decoupling problem is locally solvable iff columns of $b(x)$ are contained in $\mathcal{D}^{\max}$. If $\mathcal{M}$ is simply connected, then the disturbance decoupling problem is globally solvable iff columns of $b(x)$ are contained in $\mathcal{D}^{\max}$.

Conclusion

We have briefly described the role that differential geometric concepts played in the development of controllability, observability, minimality, approximation, and decoupling of nonlinear systems.

Disaster Response Robot

Satoshi Tadokoro

Tohoku University, Sendai, Japan

Abstract

Disaster response robots are robotic systems used for preventing outspread of disaster damage under emergent situations. Robots for natural disasters (water disaster, volcano eruption, earthquakes, flood, landslides, and fire) and man-made disasters (explosive ordnance disposal, CBRNE disasters, Fukushima-Daiichi nuclear power plant accident) are introduced. Technical challenges are described on the basis of generalized data flow.

Keywords

Rescue robot · Response robot

Introduction

Disaster response robots are robotic systems used for preventing outspread of disaster damage under emergent situations, such as for search and rescue, recovery construction, etc.

Disaster changes its state as time passes. It enters by unforeseen occurrence from prevention phase to emergency response phase, recovery phase, and revival phase. Although a disaster

response robot usually means a system for disaster response and recovery in a narrow sense, a system used in every phase of disaster can be called a disaster response robot in a broad sense.

When parties of firefighters and military respond to disaster, robots are one of the technical equipment. The purposes of robots are (1) to perform tasks impossible/difficult by human and conventional equipment, (2) to reduce responders' risk for preventing secondary damage, and (3) to improve rapidness/efficiency of tasks, by using remote/automatic robot equipment.

Response Robots for Natural Disasters

Water Disaster

Underwater robots (ROV, remotely operated vehicle) are deployed to responder organizations in preparation for water damage such as at tsunami, flood, cataract, and accidents in the sea and rivers. They are equipped with cameras and sonars and remotely controlled by crews via tether from land or shipboard within several tens meters area for victim search and damage investigation. At Great Eastern Japan Earthquake in 2011, the Self-Defense Force and volunteers of the International Rescue System Institute (IRS) and Center for Robot-Assisted Search and Rescue (CRASAR) used various types of ROVs such as SARbot shown in Fig. 1 for victim search and debris investigation in port.

Volcano Eruption

In order to reduce risk of monitoring and recovery construction at volcano eruption, application of robotics and remote systems is highly expected. Various types of UAVs (unmanned aerial vehicles) such as small-size robot helicopters and airplanes have been used for this purpose. Unmanned construction system consists of tele-operated robot backhoes, trucks, and bulldozers with wireless relaying cars and camera vehicles as shown in Fig. 2 and is remotely controlled

Disaster Response Robot, Fig. 2 Unmanned construction system. (By courtesy of Society for Unmanned Construction Systems) http://www.kenmukyou.gr.jp/f_souti.htm

from an operator vehicle. It has been used since the 1990 for remote civil engineering works from a distance of a few kilometers.

Structural Collapse by Earthquakes, Landslides, etc.

Small-sized UGVs (unmanned ground vehicles) were developed for victim search and monitoring in confined space of collapsed buildings and underground structures. VGTV-Xtreme shown in Fig. 3 is a tracked vehicle remotely operated via a tether. It was used for victim search at mine accidents and the 9.11 terror. Active Scope Camera shown in Fig. 4 is a serpentine robot like a fiberscope and was used for forensic investigation of structural collapse accidents.

Fire

Large-scale fires of chemical plants and forests sometimes have a high risk, and firefighters cannot approach near them. Remote-controlled robots with firefighting nozzles for water and chemical extinguishing agents are deployed. Large-size robots can discharge large volume of the fluid with water cannon, and small-size ones

have better mobility. Dragon Firefighter (Fig. 5) is a flying hose robot for extinguishing fire in confined space to minimize the risk of human firefighters at the operation inside.

Flood and Landslide

Unmanned aerial vehicles are effective tools for gathering overview information of flood and landslide where human responders cannot access or need time to cover wide damaged area. Captured 2D/3D images as shown in Fig. 6 are used for identifying damaged area, finding victims, estimating the amount of damage, and supporting recovery.

Response Robots for Man-Made Disasters

Explosive Ordnance Disposal (EOD)

Detection and disposal of explosive ordnance is one of the most dangerous tasks. TALON, PackBot, and Telemex are widely used in military and explosive ordnance disposal teams worldwide. Telemex has an arm with seven

degrees of freedom on a tracked vehicle with four sub-tracks as shown in Fig. 7. It can observe narrow spaces like overhead lockers of airplanes and bottom of automobiles by cameras, manipulate objects by the arm, and deactivate explosives by a disrupter.

CBRNE Disasters

CBRNE (chemical, biological, radiological, nuclear, and explosive) disasters have a high

risk and can cause large-scale damage because human cannot detect contamination by the hazmat (hazardous materials). Application of robotic systems is highly expected for this disaster. PackBot has sensors for toxic industrial chemicals (TIC), blood agents, blister agents, volatile organic compounds (VOCs), radiation, etc. as options and can measure the hazmat in dangerous confined spaces (Fig. 8). Quince was developed for research into technical issues of

Fukushima-Daiichi Nuclear Power Plant Accident

At Fukushima-Daiichi nuclear power plant accident caused by tsunami in 2011, various disaster response robots were applied. They contributed to the cool shutdown and decommissioning of the plant. For example, PackBot and Quince gave essential data for task planning by shooting images and radiation measurement in nuclear reactor buildings there. Unmanned construction system removed debris outdoors that were contaminated by radiological materials and reduced the radiation rate there significantly.

Groupe INTRA in France and KHG in Germany are organizations for responding nuclear plant accidents. They are equipped with robots and remote-controlled construction machines for radiation measurement, decontamination, and constructions in emergency. In Japan, the Assist Center for Nuclear Emergencies was established after the Fukushima accident.

Many types of remote systems (robots), such as PMORPH (Fig. 10), have been applied for preventing exposure to radiation at the decommissioning work of the plant toward removal of fuel debris.

Disaster Response Robot, Fig. 9 Quince. (By courtesy of International Rescue System Institute)

UGVs at CBRNE disasters and has high mobility on rough terrain (Fig. 9).

Summary and Future Directions

Data flow of disaster response robots is generally described by a feedback system as shown in Fig. 11. Robots change the states of objects and

environment by movement and task execution. Sensors measure and recognize them, and their feedback enables the robots autonomous motion and work. The sensed data are shown to operators via communication, data processing, and a human interface. The operators give commands of motion and work to the system via the human interface. The system recognizes and transmits them to the robot.

Each functional block has its own technical challenges to be fulfilled under extreme environments of disaster space in response to the objectives and the conditions. They should be solved technically in order to improve the robot performance. They include insufficient mobility in disaster spaces (steps, gaps, slippage, narrow space, obstacles, etc.), deficient workability (dexterity, accuracy, speed, force, work space, etc.), poor sensors and sensor data processing (image, recognition, etc.), lack of reliability and

performance of autonomy (robot intelligence, multiagent collaboration, etc.), issues of wireless and wired communication (instability, delay, capacity, tether handling, etc.), operators' limitations (situation awareness, decision ability, fatigue, mistake, etc.), basic performances (explosion proof, weight, durability, portability, etc.), and system integration that combines the components into the solution. Mission critical planning and execution including human factors, training, role sharing, logistics, etc. have to be considered at the same time.

Research into systems and control is expected to solve the abovementioned challenges of components and systems. For example, intelligent control is essential for mobility and workability under extreme conditions, control of feedback systems including long delay and dynamic instability, control of human-in-loop systems, and system integration of heterogeneous systems which are important research topics of systems and control.

In the research field of disaster robotics, various competitions of practical robots have been held, e.g., RoboCupRescue targeting CBRNE disasters, ELROB and euRathlon for field activities, MAGIC for multi-robot autonomy, DARPA Robotics Challenge for humanoid in nuclear disasters, and World Robot Summit Disaster Robotics Category for plant and tunnel disasters. They challenge to solve the abovementioned technical issues under different themes with providing practical test bed of advanced technologies.

Discrete Event Systems and Hybrid Systems, Connections Between

Alessandro Giua
 DIEE, University of Cagliari, Cagliari, Italy
 LSIS, Aix-en-Provence, France

Abstract

The causes of the complex behavior typical of hybrid systems are multifarious and are commonly explained in the literature using paradigms that are mainly focused on the connections between time-driven and hybrid

systems. In this entry, we recall some of these paradigms and further explore the connections between discrete event and hybrid systems from other perspectives. In particular, the role of abstraction in passing from a hybrid model to a discrete event one and vice versa is discussed.

Keywords

Hybrid system · Logical discrete event system · Timed discrete event system

Introduction

Hybrid systems combine the dynamics of both *time-driven systems* and *discrete event systems*.

The evolution of a *time-driven system* can be described by a differential equation (in continuous time) or by a difference equation (in discrete time). An example of such a system is the tank shown in Fig. 1 whose behavior, assuming the tank is not full, is ruled in continuous time t by the differential equation

$$\frac{d}{dt}V(t) = q_1(t) - q_2(t)$$

where V is the volume of liquid and q_1 and q_2 are, respectively, the input and output flow.

A *discrete event system* (Lafortune and Cassandras 2007; Seatzu et al. 2012) evolves in accordance with the abrupt occurrence, at possibly unknown irregular intervals, of physical events. Its states may have logical or symbolic, rather than numerical, values that change in response to events which may also be described in nonnumerical terms. An example of such a system is a robot that loads parts on a conveyor, whose behavior is described by the automaton in Fig. 2. The robot can be “idle,” “loading” a part, or in an “error” state when a part is incorrectly positioned. The events that drive its evolution are a (grasp a part), b (part correctly loaded), c (part incorrectly positioned), and d (part repositioned). In a *logical* discrete event system (► [Supervisory Control of Discrete-Event Systems](#)), the timing of event occurrences are ignored, while in a *timed*

Discrete Event Systems and Hybrid Systems, Connections Between,
Fig. 1 A tank

Discrete Event Systems and Hybrid Systems, Connections Between,
Fig. 2 A machine with failures

discrete event system (► [Models for Discrete Event Systems: An Overview](#)), they are described by means of a suitable timing structure.

In a *hybrid system* (► [Hybrid Dynamical Systems, Feedback Control of](#)), time-driven and event-driven evolutions are simultaneously present and mutually dependent. As an example, consider a room where a thermostat maintains the temperature $x(t)$ between $x_a = 20^\circ\text{C}$ and $x_b = 22^\circ\text{C}$ by turning a heat pump on and off. Due to the exchange with the external environment at temperature $x_e \ll x(t)$, when the pump is off, the room temperature derivative is

$$\frac{d}{dt}x(t) = -k[x(t) - x_e]$$

where k is a suitable coefficient, while when the pump is on, the room temperature derivative is

$$\frac{d}{dt}x(t) = h(t) - k[x(t) - x_e]$$

where the positive term $h(t)$ is due to the heat pump. The hybrid automaton that describes this system is shown in Fig. 3.

The causes of the complex behavior typical of hybrid systems are multifarious, and among the paradigms commonly used in the literature to describe them, we mention three.

- *Logically controlled systems.* Often, a physical system with a time-driven evolution is controlled in a feedback loop by means of a controller that implements discrete computations and event-based logic. This is the case of the thermostat mentioned above. Classes of systems that can be described by this paradigm are *embedded systems* or, when the feedback loop is closed through a communication network, *cyber-physical systems*.
- *State-dependent mode of operation.* A time-driven system can have different modes of evolution depending on its current state. As an example, consider a bouncing ball. While the ball is above the ground (vertical position $h > 0$) its behavior is that of a falling body subject to a constant gravitational force. However, when the ball collides with the ground (vertical position $h = 0$), its behavior is that of a (partially) elastic body that bounces up.

Discrete Event Systems and Hybrid Systems, Connections Between, Fig. 3 Hybrid automaton of the thermostat

Classes of systems that can be described by this paradigm are *piecewise affine systems* and *linear complementarity system*.

- *Variable structure systems*. Some systems may change their structure assuming different configuration, each characterized by a different behavior. As an example, consider a multicell voltage converter composed by a cascade of elementary commutation cells: controlling some switches, it is possible to insert or remove cells so as to produce a desired output voltage signal. Classes of systems that can be described by this paradigm are *switched systems*.

While these are certainly appropriate and meaningful paradigms, they are mainly focused on the connections between time-driven and hybrid systems. In the rest of this entry, we will discuss the connections between discrete event and hybrid systems from other different perspectives. The focus is strictly on modeling, thus approaches for analysis or control will not be discussed.

From Hybrid Systems to Discrete Event System by Modeling Abstraction

A *system* is a physical object, while a *model* is a (more or less accurate) mathematical description of its behavior that captures those features that are deemed mostly significant. In the previous pages, we have introduced different classes of systems, such as “time-driven systems,” “discrete event systems,” and “hybrid systems,” but properly speaking, this taxonomy pertains to the models because the terms “time driven,” “discrete event,” or “hybrid” should be used to classify the mathematical description and not the physical object.

Discrete Event Systems and Hybrid Systems, Connections Between, Fig. 4 Logical discrete event model of the thermostat

According to this view, a discrete event model is often perceived as a high-level description of a physical system where the time-driven dynamics are ignored or, at best, approximated by a timing structure. This procedure to derive a simpler model in a way that preserves the properties being analyzed while hiding the details that are of no interest is called *abstraction* (Alur et al. 2000).

Consider, as an example, the thermostat in Fig. 3. In such a system, the time-driven evolution determines a change in the temperature, which in turn – reaching a threshold – triggers the occurrence of an event that changes the discrete state. Assume one does not care about the exact form this triggering mechanism takes and is only interested in determining if the heat pump is turned on or off. In such a case, we can completely *abstract* the time-driven evolution obtaining a logical discrete event model such as the automaton in Fig. 4, where label *a* denotes the event *the temperature drops below 20°C* and label *b* denotes the event *the temperature raises over 22°C*.

For some purposes, e.g., to determine the utilization rate of the heat pump and thus its operating cost, the model in Fig. 4 is inadequate. In such a case, one can consider a less coarse abstraction of the hybrid model in Fig. 3 obtaining a timed discrete event model such as the automaton in Fig. 4. Here, to each event is associated a firing delay: as an example, δ_a represents the time it takes – when the pump is

off – to cool down until the lower temperature threshold is reached and event a occurs. The delay may be a deterministic value or even a random one to take into account the uncertainty due to non-modeled time-varying parameters such as the temperature of the external environment. Note that a new state (START) and a new event b' have now been introduced to capture the transient phase in which the room temperature, from the initial value $x(0) = 15^\circ\text{C}$, reaches the higher temperature threshold: in fact, event b' has a delay greater than the delay of event b .

Timed Discrete Event Systems Are Hybrid Systems

Properly speaking, all timed discrete event systems may also be seen as hybrid systems if one considers the dynamics of the timers – that specify the event occurrence – as elementary time-driven evolutions. In fact, the simplest model of hybrid systems is the *timed automaton* introduced by Alur and Dill (1994) whose main feature is the fact that each continuous variable $x(t)$ has a constant derivative $\dot{x}(t) = 1$ and thus can only describe the passage of time. Incidentally, we note that the term “timed automaton” is also used in the area of discrete event systems (Lafortune and Cassandras 2007) to denote an automaton in which a timing structure is associated to the events: such an example was shown in Fig. 5. To avoid any confusion, in the following, we denote the former model *Alur-Dill automaton* and the latter model *timed DES automaton*.

In Fig. 6 is shown an Alur-Dill automaton that describes the thermostat, where the time-driven dynamics have been abstracted and only the timing of event occurrence is modeled as in

Discrete Event Systems and Hybrid Systems, Connections Between, Fig. 5 Timed discrete event model of the thermostat

the timed DES automaton in Fig. 5. The only continuous variable is the value of a timer δ : when it goes beyond a certain threshold (e.g., $\delta > \delta_a$), an event occurs (e.g., event a) changing the discrete state (e.g., from OFF to ON) and resetting the timer to zero.

It is rather obvious that the behavior of the Alur-Dill automaton in Fig. 6 is equivalent to the behavior of timed DES automaton in Fig. 5. In the former model, the notion of time is encoded by means of an explicit continuous variable δ . In the latter model, the notion of time is implicitly encoded by the timer that during an evolution will be associated to each event. In both cases, however, the overall state of the systems is described by a pair $(\ell(t), x(t))$ where the first element ℓ takes value in a discrete set $\{START, ON, OFF\}$ and the second element is a vector (in this particular case with a single component) of timer valuations.

It should be pointed out that an Alur-Dill automaton may have a more complex structure than that shown in Fig. 6: as an example, the guard associated to a transition, i.e., the values of the timer that enable it, can be an arbitrary rectangular set. However, the same is also true for a timed discrete event system: several policies can be used to define the time intervals enabling an event (enabling policy) or to specify when a timer is reset (memory policy) (Ajmone Marsan et al. 1995). Furthermore, timed discrete event system can have arbitrary stochastic timing structures (e.g., semi-Markovian processes, Markov chains, and queuing networks (Lafortune and Cassandras 2007)), not to mention the possibility of having an infinite discrete state space (e.g., timed Petri nets (Ajmone Marsan et al. 1995; David and Alla 2004)). As a result, we can say that timed DES automata are far more general than Alur-Dill automata and represent a meaningful subclass of hybrid systems.

From Discrete Event System to Hybrid Systems by Fluidization

The computational complexity involved in the analysis and optimization of real-scale problems

Discrete Event Systems and Hybrid Systems, Connections Between, Fig. 6 Alur-Dill automaton of the thermostat

often becomes intractable with discrete event models due to the very large number of reachable states, and a technique that has shown to be effective in reducing this complexity is called *fluidization* (► [Applications of Discrete Event Systems](#)). It should be noted that the derivation of a fluid (i.e., hybrid) model from a discrete event one is yet an example of abstraction albeit going in opposite direction with respect to the examples discussed in the section “[From Hybrid Systems to Discrete Event System by Modeling Abstraction](#)” above.

The main drive that motivated the fluidization approach derives from the observation that some discrete event systems are “heavily populated” in the sense that there are many identical items in some component (e.g., clients in a queue). Fluidization consists in replacing the integer counter of the number of items by a real number and in approximating the “fast” discrete event dynamics that describe how the counter changes by a continuous dynamics. This approach has been successfully used to study the performance optimization of fluid-queuing networks (Cassandras and Lygeros 2006) or Petri net models (Balduzzi et al. 2000; David and Alla 2004; Silva and Recalde 2004) with applications in domains such as manufacturing systems and communication networks. We also remark that in general, different fluid approximations are necessary to describe the same system, depending on its discrete state, e.g., in the manufacturing domain, machines working or down, buffers full or empty, and so on. Thus, the resulting model can be better described as a hybrid model, where different time-driven dynamics are associated to different discrete states.

There are many advantages in using fluid approximations. First, there is the possibility of considerable increase in computational efficiency

because the simulation of a fluid model can often be performed much faster than that of its discrete event counterpart. Second, fluid approximations provide an aggregate formulation to deal with complex systems, thus reducing the dimension of the state space. Third, the resulting simple structures often allow explicit computation of performance measures. Finally, some design parameters in fluid models are continuous; hence, it is possible to use gradient information to speed up optimization and to perform sensitivity analysis (Balduzzi et al. 2000); in many cases, it has also been shown that fluid approximations do not introduce significant errors when carrying out performance analysis via simulation (► [Perturbation Analysis of Discrete Event Systems](#)).

Definition

Discrete optimal control is a branch of mathematics which studies optimization procedures for controlled discrete-time models, that is, the optimization of a performance index associated to a discrete-time control system.

Motivation

Optimal control theory is a mathematical discipline with innumerable applications in both science and engineering. Discrete optimal control is concerned with control optimization for discrete-time models. Recently, in discrete optimal control theory, a great interest has appeared in developing numerical methods to optimally control real mechanical systems, as for instance, autonomous robotic vehicles in natural environments such as robotic arms, spacecrafts, or underwater vehicles.

During the last years, a huge effort has been made for the comprehension of the fundamental geometric structures appearing in dynamical systems, including control systems and optimal control systems. This new geometric understanding of those systems has made possible the construction of suitable numerical techniques for integration. A collection of ad hoc numerical methods are available for both dynamical and control systems. These methods have grown up accordingly with the needs in research coming from different fields such as physics and engineering. However, a new breed of ideas in numerical analysis has started recently. They incorporate the geometry of the systems into the analysis and that allows faster and more accurate algorithms and with less spurious effects than the traditional ones. All this gives birth to a new field called Geometric Integration (Hairer et al. 2002). For instance, numerical integrators for Hamiltonian systems should preserve the symplectic structure underlying the geometry of the system. If so, they are called symplectic integrators.

Another approach used by more and more authors is based on the theory of discrete mechanics and variational integrators to obtain geometric integrators preserving some of the

geometry of the original system (Marsden and West 2001; Hussein et al. 2006; Wendlandt and Marsden 1997a, b) (see also the section “Discrete Mechanics”). These geometric integrators are easily adapted and applied to a wide range of mechanical systems: forced or dissipative systems, holonomically constrained systems, explicitly time-dependent systems, reduced systems with frictional contact, nonholonomic dynamics, and multisymplectic field theories, among others.

As before, in optimal control theory, it is necessary to distinguish two kinds of numerical methods: the so-called direct and indirect methods. If we use direct methods, we first discretize the state and control variables, control equations, and cost functional, and then we solve a nonlinear optimization problem with constraints given by the discrete control equations, additional constraints, and boundary conditions (Bock and Plitt 1984; Bonnans and Laurent-Varin 2006; Hager 2001; Pytlak 1999). In this case, we typically need to solve a system of the type (see the section “Formulation of a General Discrete Optimal Control Problem”)

$$\begin{cases} \text{minimize } F(X) \\ \text{with } \Psi(X) = 0 \\ \Phi(X) \geq 0 \end{cases} \quad X = (q^0, \dots, q^N, u_1, \dots, u_N)$$

On the other hand, indirect methods consist of solving numerically the boundary value problem obtained from the equations after applying Pontryagin’s Maximum Principle.

The combination of direct methods and discrete mechanics allows to obtain numerical control algorithms which are geometric structure preserving and exhibit a good long-time behavior (Bloch et al. 2013; Junge and Ober-Blöbaum 2005; Junge et al. 2006; Kobilarov 2008; Jiménez et al. 2013; Leyendecker et al. 2007; Ober-Blöbaum 2008; Ober-Blöbaum et al. 2011). Furthermore, it is possible to adapt many of the techniques used for continuous control mechanical systems to the design of quantitative and qualitative accurate numerical methods for optimal control methods (reduction by

symmetries, preservation of geometric structures, Lie group methods, etc.).

Formulation of a General Discrete Optimal Control Problem

Let M be an n -dimensional manifold, x denote the state variables in M for an agent’s environment, and $u \in U \subset \mathbb{R}^m$ be the control or action that the agent chooses to accomplish a task or objective. Let $f_d(x, u) \in M$ be the resulting state after applying the control u to the state x . For instance, x may be the configuration of a vehicle at time t and u its fuel consumption, and then $f_d(x, u)$ is the new configuration of the vehicle at time $t + h$, with $t, h > 0$. Of course, we want to minimize the fuel consumption. Hence, the optimal control problem consists of finding the cheapest way to move the system from a given initial position to a final state. The problem can be mathematically described as follows: find a sequence of controls $(u_0, u_1, \dots, u_{N-1})$ and a sequence of states $(x_0, x_1, \dots, x_N)$ such that

$$x_{k+1} = f_d(k, x_k, u_k), \quad (1)$$

where $x_k \in M, u_k \in U$, and the total cost

$$C_d = \sum_{k=0}^{N-1} C_d(k, x_k, u_k) + \phi_d(N, x_N) \quad (2)$$

is minimized where ϕ_d is a function of the final time and state at the final time (the terminal payoff) and C_d is a function depending on the discrete time, the state, and the control at each intermediate discrete time k (the running payoff).

To solve the discrete optimal control problem determined by Eqs. (1) and (2), it is possible to use the classical Lagrangian multiplier approach. In this case, we consider the control equations (1) as constraint equations associating a Lagrange multiplier to each constraint. Assume for simplicity that $M = \mathbb{R}^n$. Then, we construct the augmented cost function

$$\tilde{C}_d = \sum_{k=0}^{N-1} \left[p_{k+1} (x_{k+1} - f_d(k, x_k, u_k)) - C_d(k, x_k, u_k) \right] - \Phi_d(N, x_N) \quad (3)$$

where $p_k \in \mathbb{R}^n$, $k = 1, \dots, N$, are considered as the Lagrange multipliers. The notation xy is used for the scalar (inner) product $x \cdot y$ of two vectors in $\mathbb{R}^n$.

From the *pseudo-Hamiltonian function*

$$H_d(k, x_k, p_{k+1}, u_k) = p_{k+1} f_d(k, x_k, u_k) - C_d(k, x_k, u_k),$$

we deduce the necessary conditions for a constrained minimum:

$$\begin{aligned} x_{k+1} &= \frac{\partial H_d}{\partial p}(k, x_k, p_{k+1}, u_k) \\ &= f_d(k, x_k, u_k) \end{aligned} \quad (4)$$

$$\begin{aligned} p_k &= \frac{\partial H_d}{\partial q}(k, x_k, p_{k+1}, u_k) \\ &= p_{k+1} \frac{\partial f_d}{\partial q}(k, x_k, u_k) \\ &\quad - \frac{\partial C_d}{\partial q}(k, x_k, u_k) \end{aligned} \quad (5)$$

$$\begin{aligned} 0 &= \frac{\partial H_d}{\partial u}(k, x_k, p_{k+1}, u_k) \\ &= p_{k+1} \frac{\partial f_d}{\partial u}(k, x_k, u_k) \\ &\quad - \frac{\partial C_d}{\partial u}(k, x_k, u_k) \end{aligned} \quad (6)$$

where $0 \leq k \leq N-1$. Moreover, we have some boundary conditions

$$x_0 \text{ is given and } p_N = -\frac{\partial \Phi_d}{\partial q}(N, x_N) \quad (7)$$

The variable p_k is called the costate of the system and Eq. (5) is called the adjoint equation. Observe that the recursion of x_k given by Eq. (4) develops forward in the discrete time, but the recursion of the costate variable is backward in the discrete time.

In the sequel, it is assumed the following regularity condition:

$$\det \left(\frac{\partial^2 H_d}{\partial u^a \partial u^b} \right) \neq 0$$

where $1 \leq a, b \leq m$, and $(u^a) \in U \subseteq \mathbb{R}^m$. Applying the implicit function theorem, we obtain from Eq. (6) that locally $u_k = g(k, x_k, p_{k+1})$. Defining the function

$$\begin{aligned} \tilde{H}_d : \quad \mathbb{Z} \times \mathbb{R}^{2n} &\longrightarrow \mathbb{R} \\ (k, q_k, p_{k+1}) &\longmapsto H_d(k, q_k, p_{k+1}, u_k) \end{aligned}$$

Equations (4) and (5) are rewritten as the following discrete Hamiltonian system:

$$x_{k+1} = \frac{\partial \tilde{H}_d}{\partial p}(k, x_k, p_{k+1}) \quad (8)$$

$$p_k = \frac{\partial \tilde{H}_d}{\partial q}(k, x_k, p_{k+1}) \quad (9)$$

The expression of the solutions of the optimal control problem as a discrete Hamiltonian system (under some regularity properties) is important since it indicates that the discrete evolution is preserving symplecticity. A simple proof of this fact is the following (de León et al. (2007)). Construct the following function

$$\begin{aligned} G_k(x_k, x_{k+1}, p_{k+1}) &= \tilde{H}_d(k, x_k, p_{k+1}) \\ &\quad - p_{k+1} x_{k+1}, \end{aligned}$$

with $0 \leq k \leq N-1$. For each fixed k :

$$\begin{aligned} dG_k &= \frac{\partial \tilde{H}_d}{\partial q}(k, x_k, p_{k+1}) dx_k \\ &\quad + \frac{\partial \tilde{H}_d}{\partial p}(k, x_k, p_{k+1}) dp_{k+1} \\ &\quad - p_{k+1} dx_{k+1} - x_{k+1} dp_{k+1}. \end{aligned}$$

Thus, along solutions of Eqs. (8) and (9), we have that $dG_k|_{\text{solutions}} = p_k dx_k - p_{k+1} dx_{k+1}$ which implies $dx_k \wedge dp_k = dx_{k+1} \wedge dp_{k+1}$.

In the next section, we will study the case of discrete optimal control of mechanical systems.

First, we will need an introduction to discrete mechanics and variational integrators.

Discrete Mechanics

Let Q be an n -dimensional differentiable manifold with local coordinates (q^i) , $1 \leq i \leq n$. We denote by TQ its tangent bundle with induced coordinates $(q^i, \dot{q}^i)$. Let $L: TQ \rightarrow \mathbb{R}$ be a Lagrangian function; the associated Euler–Lagrange equations are given by

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{q}^i} \right) - \frac{\partial L}{\partial q^i} = 0, \quad 1 \leq i \leq n. \quad (10)$$

These equations are a system of implicit second-order differential equations. Assume that the Lagrangian is **regular**, that is, the matrix $\left(\frac{\partial^2 L}{\partial \dot{q}^i \partial \dot{q}^j} \right)$ is non-singular. It is well known that the origin of these equations is variational (see Marsden and West 2001). Variational integrators retain this variational character and also some of the key geometric properties of the continuous system, such as symplecticity and momentum conservation (see Hairer et al. 2002 and references therein). In the following, we summarize the main features of this type of numerical integrators (Marsden and West 2001). A **discrete Lagrangian** is a map $L_d: Q \times Q \rightarrow \mathbb{R}$, which may be considered as an approximation of the integral action defined by a continuous Lagrangian $L: TQ \rightarrow \mathbb{R}$: $L_d(q_0, q_1) \approx \int_0^h L(q(t), \dot{q}(t)) dt$ where $q(t)$ is a solution of the Euler–Lagrange equations for L with $q(0) = q_0$, $q(h) = q_1$, and $h > 0$ being enough small.

Remark 1 The Cartesian product $Q \times Q$ is equipped with an interesting differential structure, called Lie groupoid, which allows the extension of variational calculus to more general settings (see Marrero et al. 2006, 2010 for more details).

Define the **action sum** $S_d: Q^{N+1} \rightarrow \mathbb{R}$, corresponding to the Lagrangian L_d by $S_d = \sum_{k=1}^N L_d(q_{k-1}, q_k)$, where $q_k \in Q$ for $0 \leq k \leq N$ and N is the number of steps. The discrete

variational principle states that the solutions of the discrete system determined by L_d must extremize the action sum given fixed endpoints q_0 and q_N . By extremizing S_d over q_k , $1 \leq k \leq N-1$, we obtain the system of difference equations

$$D_1 L_d(q_k, q_{k+1}) + D_2 L_d(q_{k-1}, q_k) = 0, \quad (11)$$

or, in coordinates,

$$\frac{\partial L_d}{\partial x^i}(q_k, q_{k+1}) + \frac{\partial L_d}{\partial y^i}(q_{k-1}, q_k) = 0,$$

where $1 \leq i \leq n$, $1 \leq k \leq N-1$, and x, y denote the n -first and n -second variables of the function L_d , respectively.

These equations are usually called the **discrete Euler–Lagrange equations**. Under some regularity hypotheses (the matrix $D_{12} L_d(q_k, q_{k+1})$ is regular), it is possible to define a (local) discrete flow $\Upsilon_{L_d}: Q \times Q \rightarrow Q \times Q$, by $\Upsilon_{L_d}(q_{k-1}, q_k) = (q_k, q_{k+1})$ from (11). Define the discrete Legendre transformations associated to L_d as

$$\begin{aligned} \mathbb{F}^- L_d: Q \times Q &\rightarrow T^*Q \\ (q_0, q_1) &\mapsto (q_0, -D_1 L_d(q_0, q_1)), \\ \mathbb{F}^+ L_d: Q \times Q &\rightarrow T^*Q \\ (q_0, q_1) &\mapsto (q_1, D_2 L_d(q_0, q_1)), \end{aligned}$$

and the discrete Poincaré–Cartan 2-form $\omega_d = (\mathbb{F}^+ L_d)^* \omega_Q = (\mathbb{F}^- L_d)^* \omega_Q$, where ω_Q is the canonical symplectic form on T^*Q . The discrete algorithm determined by Υ_{L_d} preserves the symplectic form ω_d , i.e., $\Upsilon_{L_d}^* \omega_d = \omega_d$. Moreover, if the discrete Lagrangian is invariant under the diagonal action of a Lie group G , then the discrete momentum map $J_d: Q \times Q \rightarrow \mathfrak{g}^*$ defined by

$$\begin{aligned} \langle J_d(q_k, q_{k+1}), \xi \rangle &= \langle D_2 L_d(q_k, q_{k+1}), \\ &\quad \xi_Q(q_{k+1}) \rangle \end{aligned}$$

is preserved by the discrete flow. Therefore, these integrators are symplectic-momentum preserving. Here, ξ_Q denotes the fundamental vector field determined by $\xi \in \mathfrak{g}$, where $\mathfrak{g}$ is the Lie

algebra of G . As stated in Marsden and West (2001), discrete mechanics is inspired by discrete formulations of optimal control problems (see Cadzow 1970; Jordan and Polak 1964; Hwang and Fan 1967).

Discrete Optimal Control of Mechanical Systems

Consider a mechanical system whose configuration space is an n -dimensional differentiable manifold Q and whose dynamics is determined by a Lagrangian $L : TQ \rightarrow \mathbb{R}$. The control forces are modeled as a mapping $f : TQ \times U \rightarrow T^*Q$, where $f(v_q, u) \in T_q^*Q$, $v_q \in T_qQ$ and $u \in U$, being U the control space. Observe that this last definition also covers configuration and velocity-dependent forces such as dissipation or friction (see Ober-Blobaum et al. 2011).

The motion of the mechanical system is described by applying the principle of **Lagrange–d’Alembert**, which requires that the solutions $q(t) \in Q$ must satisfy

$$\begin{aligned} \delta \int_0^T L(q(t), \dot{q}(t)) dt \\ + \int_0^T f(q(t), \dot{q}(t), u(t)) \delta q(t) dt = 0, \end{aligned} \quad (12)$$

where $(q, \dot{q})$ are the local coordinates of TQ and where we consider arbitrary variations $\delta q(t) \in T_{q(t)}Q$ with $\delta q(0) = 0$ and $\delta q(T) = 0$ (since we are prescribing fixed initial and final conditions $(q(0), \dot{q}(0))$ and $(q(T), \dot{q}(T))$).

As we consider an optimal control problem, the forces f must be chosen, if they exist, as the ones that extremize the **cost functional**:

$$\begin{aligned} \int_0^T C(q(t), \dot{q}(t), u(t)) dt \\ + \Phi(q(T), \dot{q}(T), u(T)), \end{aligned} \quad (13)$$

where $C : TQ \times U \rightarrow \mathbb{R}$.

The optimal equations of motion can now be derived using Pontryagin’s Maximum Principle.

In general, it is not possible to explicitly integrate these equations. Then, it is necessary to apply a numerical method. In this work, using discrete variational techniques, we first discretize the Lagrange–d’Alembert principle and then the cost functional. We obtain a numerical method that preserves some geometric features of the original continuous system as described in the sequel.

Discretization of the Lagrangian and Control Forces

To discretize this problem, we replace the tangent space TQ by the Cartesian product $Q \times Q$ and the continuous curves by sequences $q_0, q_1, \dots, q_N$ (we are using N steps, with time step h fixed, in such a way $t_k = kh$ and $Nh = T$). The discrete Lagrangian $L_d : Q \times Q \rightarrow \mathbb{R}$ is constructed as an approximation of the action integral in a single time step (see Marsden and West 2001), that is,

$$L_d(q_k, q_{k+1}) \approx \int_{kh}^{(k+1)h} L(q(t), \dot{q}(t)) dt.$$

We choose the following discretization for the external forces: $f_d^\pm : Q \times Q \times U \rightarrow T^*Q$, where $U \subset \mathbb{R}^m$, $m \leq n$, such that

$$\begin{aligned} f_d^-(q_k, q_{k+1}, u_k) &\in T_{q_k}^*Q, \\ f_d^+(q_k, q_{k+1}, u_k) &\in T_{q_{k+1}}^*Q. \end{aligned}$$

f_d^+ and f_d^- are right and left discrete forces (see Ober-Blobaum et al. 2011).

Discrete Lagrange–d’Alembert Principle

Given such forces, we define the discrete Lagrange–d’Alembert principle, which seeks sequences $\{q_k\}_{k=0}^N$ that satisfy

$$\begin{aligned} \delta \sum_{k=0}^{N-1} L_d(q_k, q_{k+1}) \\ + \sum_{k=0}^{N-1} \left(f_d^-(q_k, q_{k+1}, u_k) \delta q_k \right. \\ \left. + f_d^+(q_k, q_{k+1}, u_k) \delta q_{k+1} \right) = 0, \end{aligned}$$

for arbitrary variations $\{\delta q_k\}_{k=0}^N$ with $\delta q_0 = \delta q_N = 0$. After some straightforward manipulations, we arrive to the forced discrete Euler–Lagrange equations

$$\begin{aligned} D_2 L_d(q_{k-1}, q_k) + D_1 L_d(q_k, q_{k+1}) \\ + f_d^+(q_{k-1}, q_k, u_{k-1}) \\ + f_d^-(q_k, q_{k+1}, u_k) = 0, \end{aligned} \quad (14)$$

with $k = 1, \dots, N-1$.

Boundary Conditions

For simplicity, we assume that the boundary conditions of the continuous optimal control problem are given by $q(0) = x_0$, $\dot{q}(0) = v_0$, $q(T) = x_T$, $\dot{q}(T) = v_T$. To incorporate these conditions to the discrete setting, we use both the continuous and discrete Legendre transformations. From Marsden and West (2001), given a forced system, we can define the discrete momenta

$$\begin{aligned} \mu_k &= -D_1 L_d(q_k, q_{k+1}) - f_d^-(q_k, q_{k+1}, u_k), \\ \mu_{k+1} &= D_2 L_d(q_k, q_{k+1}) + f_d^+(q_k, q_{k+1}, u_k). \end{aligned}$$

From the continuous Lagrangian, we have the momenta

$$\begin{aligned} p_0 &= \mathbb{F}L(x_0, v_0) = (x_0, \frac{\partial L}{\partial v}(x_0, v_0)) \\ p_T &= \mathbb{F}L(x_T, v_T) = \left(x_T, \frac{\partial L}{\partial v}(x_T, v_T)\right) \end{aligned}$$

Therefore, the natural choice of boundary conditions is

$$\begin{aligned} x_0 &= q_0, \quad x_T = q_N \\ \mathbb{F}L(x_0, v_0) &= -D_1 L_d(q_0, q_1) - f_d^-(q_0, q_1, u_0) \\ \mathbb{F}L(x_T, v_T) &= D_2 L_d(q_{N-1}, q_N) \\ &\quad + f_d^+(q_{N-1}, q_N, u_{N-1}) \end{aligned}$$

that we add to the discrete optimal control problem.

Discrete Cost Function

We can also approximate the cost functional (13) in a single time step h by

$$\begin{aligned} C_d(q_k, q_{k+1}, u_k) \\ \approx \int_{kh}^{(k+1)h} C(q(t), \dot{q}(t), u(t)) dt, \end{aligned}$$

yielding the **discrete cost functional**:

$$\sum_{k=0}^{N-1} C_d(q_k, q_{k+1}, u_k) + \Phi_d(q_{N-1}, q_N, u_{N-1}).$$

Discrete Optimal Control Problem

With all these elements, we have the following discrete optimal control problem:

$$\begin{aligned} \min \sum_{k=0}^{N-1} C_d(q_k, q_{k+1}, u_k) \\ + \Phi_d(q_{N-1}, q_N, u_{N-1}) \end{aligned}$$

subject to

$$\begin{aligned} D_2 L_d(q_{k-1}, q_k) + D_1 L_d(q_k, q_{k+1}) \\ + f_d^+(q_{k-1}, q_k, u_{k-1}) + f_d^-(q_k, q_{k+1}, u_k) = 0, \\ x_0 = q_0, \quad x_T = q_N \\ \frac{\partial L}{\partial v}(x_0, v_0) = -D_1 L_d(q_0, q_1) - f_d^-(q_0, q_1, u_0) \\ \frac{\partial L}{\partial v}(x_T, v_T) = D_2 L_d(q_{N-1}, q_N) \\ + f_d^+(q_{N-1}, q_N, u_{N-1}) \end{aligned}$$

with $k = 1, \dots, N-1$ (see Jiménez et al. 2013; Jiménez and Martín de Diego 2010 for a modification of these equations admitting piecewise controls).

The system now is a constrained nonlinear optimization problem, that is, it corresponds to the minimization of a function subject to algebraic constraints. The necessary conditions for optimality are derived applying nonlinear programming optimization. For the concrete implementation, it is possible to use sequential quadratic programming (SQP) methods to numerically solve the nonlinear optimization problem (Ober-Blöbaum et al. 2011).

Optimal Control Systems with Symmetries

In many interesting cases, the continuous optimal control of a mechanical system is defined on a Lie group and the Lagrangian, cost function, control forces are invariant under the group action. The goal is again the same as in the previous section, that is, to move the system from its current state to a desired state in an optimal way. In this particular case, it is possible to adapt the contents of the section “[Discrete Mechanics](#)” in a similar way to the continuous case (from the standard Euler–Lagrange equations to the Euler–Poincaré equations) and to produce the so-called Lie group variational integrators. These methods preserve the Lie group structure avoiding the use of local charts, projections, or constraints. Based on these methods, for the case of controlled mechanical systems, we produce the discrete Euler–Poincaré equations with controls and the discrete cost function. Consequently, it is possible to deduce necessary optimality conditions for this class of invariant systems (see Bloch et al. 2009; Bou-Rabee and Marsden 2009; Kobilarov and Marsden 2011; Hussein et al. 2006).

²Department of Electrical and Computer Engineering, Institute for Systems Research, University of Maryland, College Park, MD, USA

Abstract

The entry overviews theory and application of distributed estimation in networks. Distributed estimation research focuses on designing a

network of agents that estimate the state of a large-scale dynamical system, where information exchange between the agents plays a critical role. We discuss algorithms for distributed estimation that define how the agents exchange information and update their state estimates using exchanged information and sensor measurements on the system's state. We review key theoretical results on the algorithm design that find exact conditions under which the state estimate at each agent converges to the system's state and analyze the effect of disturbances in system models, sensing, and communication on estimation performance. To emphasize the importance of the research, we explain key applications of distributed estimation approaches in engineering problems such as distributed control design for maneuvering a vehicle platoon and sensor network design for monitoring wild animal groups.

Estimation over networks · Linear time-invariant system · Stability · Robust estimation

Introduction

Distributed estimation research investigates an important problem of designing a network of agents that estimate the state of a large-scale dynamical system. Each agent is equipped with a sensor to collect measurements on the system's state and exchanges information with other agents that are within its communication range. The main goal of the problem is to design a distributed algorithm that defines what information to be exchanged between agents and how each agent estimates the system's state based on exchanged information and sensor measurements.

Unlike the centralized estimator design problem, each agent accesses measurements on a small portion of the system's state; hence without communication with other agents for information

exchange, it cannot fully estimate the system's state. On the other hand, information exchange between agents is constrained by the agents' communication capability, and the state estimation through simple exchange of the measurements, which requires all-to-all communication, would not be feasible.

To address the new challenges, the research in general focuses on the following three components: (1) designing a class of parameterized distributed algorithms that define what information to be exchanged between agents and how each agent updates a state estimate using its own sensor measurements and information from its neighbors, (2) finding conditions under which there is a parameter selection for the algorithm that results in convergence of every agent's estimate to the system's state, and (3) optimizing the parameter selection to attenuate the effect of disturbances in system models, sensing, and communication on estimation performance. In this article, we review some of well-established results in literature related to each component.

As immediate applications, distributed estimation algorithms have been applied in monitoring and controlling large-scale dynamical systems. We discuss two use cases wherein the algorithms are used to design a distributed control system for maneuvering a vehicle platoon and a network of sensing devices for monitoring wild animal groups.

Concise Description of Distributed Estimation

Consider the distributed estimation problem of designing a network of M agents to infer the state of a dynamical system to be monitored and potentially to be controlled. In this section, we review models for the dynamical system and inter-agent communication and an estimation rule that specifies how each agent infers the system's state in the network. Figure 1 illustrates an overview of the distributed estimation and a comparison with the centralized estimation.

We begin by describing the system model using a state-space representation in the continuous-time domain (Some of the distributed estimation approaches reviewed in this entry are designed for discrete-time domain models. However, since techniques developed there are also applicable to the continuous-time domain models (1), for brevity, we only adopt the continuous-time representation.):

$$\dot{x}(t) = Ax(t) + Bu(t) + w_x(t), \quad x(0) = x_0 \quad (1a)$$

$$y_i(t) = C_i x(t) + w_{y_i}(t), \quad i \in \{1, \dots, M\} \quad (1b)$$

The n -dimensional real-valued vector $x(t)$ represents the state of the system, and the p -dimensional real-valued vector $u(t)$ denotes the input to the system. For each i in $\{1, \dots, M\}$, the r_i -dimensional real-valued vector $y_i(t)$ denotes

Distributed Estimation in Networks, Fig. 1 A comparison between the centralized estimation and distributed estimation. Notably, in the distributed estimation, each agent i in the network accesses the measurement $y_i(t)$

on the system's state, communicates with its neighboring agents defined by a given graph $\mathcal{G}$, and computes the state estimate $\hat{x}_i(t)$

the i -th (sensor) measurement that is available to Agent i . The variables $w_x(t)$ and $w_{y_i}(t)$ are disturbance terms representing error in modeling the system dynamics using (1a) and sensor noise associated with the measurement $y_i(t)$ as in (1b), respectively.

The main motivation that prompted the study of distributed estimation is that monitoring and controlling large-scale dynamical systems require multiple networked agents to collect sensor measurements and to share information within the network to estimate the full state of the system, which is of a substantial dimension and cannot be estimated by a single agent. The following are a few examples of such large-scale systems that can be represented by the model (1) (In addition to the examples mentioned in this entry, it is worth mentioning that the model (1) would be used to describe parameter estimation problems in networks (Kar and Moura 2013), where a parameter to be estimated can be defined as the state $x(t)$ of (1) with the selection of $A = I$, $B = 0$, and $w_x(t) = 0$, $t \geq 0$.):

1. Vehicle platoon: To improve transportation efficiency, Levine and Athans (1966) propose the idea of vehicle platooning. A vehicle platoon consists of M vehicles; each needs to be controlled to maintain relative positions with its neighboring vehicles. To model the vehicle platoon using (1), we define $x(t) = (x_1(t), \dots, x_M(t))$ where $x_i(t) = (p_i(t) - p_{i-1}(t), v_i(t))$, with $p_0(t) = 0$, that is, the position of Vehicle i relative to Vehicle $i - 1$ and the velocity of Vehicle i . The sensor measurement $y_i(t)$ in this application is a noisy measurement of $x_i(t)$. The following equations describe how the position $p_i(t)$ and velocity $v_i(t)$ change in response to the control $u_i(t)$ applied to each vehicle and how the measurement $y_i(t)$ is defined: for each i in $\{1, \dots, M\}$,

$$\dot{p}_i(t) = v_i(t) \quad (2a)$$

$$\dot{v}_i(t) = u_i(t) + w_{v_i}(t) \quad (2b)$$

$$y_i(t) = \begin{pmatrix} p_i(t) - p_{i-1}(t) \\ v_i(t) \end{pmatrix} + w_{y_i}(t) \quad (2c)$$

2. Collective mobile agent model: Consider a group of mobile agents, each is described by its position $p_i(t)$ and moving velocity $v_i(t)$ in which the velocity vector $v_i(t)$ of Agent i depends on those of other agents in the same group. To express this model using (1), we define $x(t) = (x_1(t), \dots, x_M(t))$ with $x_i(t) = (p_i(t), v_i(t))$ and $y_i(t)$ as a noisy measurement of $x_i(t)$. In particular, the state-space representations for $p_i(t)$, $v_i(t)$, and $y_i(t)$ are defined as follows: for each i in $\{1, \dots, M\}$,

$$\dot{p}_i(t) = v_i(t) \quad (3a)$$

$$\dot{v}_i(t) = \sum_{j=1}^M l_{ij} v_j(t) + w_{v_i}(t) \quad (3b)$$

$$y_i(t) = \begin{pmatrix} p_i(t) \\ v_i(t) \end{pmatrix} + w_{y_i}(t) \quad (3c)$$

where l_{ij} are constants satisfying $\sum_{j=1}^M l_{ij} = 0$ and describing the velocity coupling among the agents. (A discrete-time counterpart of the model has been used to describe the group movement of terrestrial animals (Park et al. 2019).

3. Coupled Kuramoto oscillators: The Kuramoto oscillators are described by a nonlinear dynamic model and are used to study synchronization problems in power grids (Skardal and Arenas 2015). Its linearized model can be expressed by (1) with the state $x(t)$ defined by $x(t) = (\theta_1(t), \dots, \theta_M(t))$, where $\theta_i(t)$ is the phase of the i -th oscillator, and the measurement $y_i(t)$ is defined as $y_i(t) = \theta_i(t)$: for each i in $\{1, \dots, M\}$,

$$\dot{\theta}_i(t) = K \sum_{j=1}^M L_{ij} \theta_j(t) + \omega_i \quad (4a)$$

$$y_i(t) = \theta_i(t) \quad (4b)$$

where K and L_{ij} are a global coupling strength and an entry of a network Laplacian matrix L , respectively. The constant ω_i

represents the natural frequency of the i -th oscillator.

The physical limitations on the agents' communication capability define the set of neighbors each agent can exchange information with and impose a graph structure on the network, which we represent by a directed graph $\mathcal{G} = (\mathbb{V}, \mathbb{E})$: The vertex set $\mathbb{V}$ represents all the agents in the network, and each edge $e = (i, j)$ in the edge set $\mathbb{E}$ denotes the feasibility of information transfer from Agent i to Agent j . The directed graph $\mathcal{G} = (\mathbb{V}, \mathbb{E})$ essentially specifies the feasibility of information exchange between agents and imposes a communication constraint on the algorithm design for distributed estimation.

The following definitions from graph theory are useful for our discussions. For each i in $\mathbb{V}$, the neighborhood set $\mathbb{N}_i$ is defined as the set of agents that can transmit information to Agent i , including Agent i itself. The graph $\mathcal{G}$ is said to be *strongly connected* if there is a directed path between every pair of agents, and a strongly connected subgraph of $\mathcal{G}$ is said to be a *source component* if there is no incoming edge from any agent outside the subgraph.

With the system model (1) and the graphical representation $\mathcal{G} = (\mathbb{V}, \mathbb{E})$ of the network, we now describe a distributed estimation algorithm that specifies how each agent computes its state estimate $\hat{x}_i(t)$. One of the technical challenges in the algorithm design is mainly due to the constraint that communication between the agents is restricted by $\mathcal{G}$ and, hence, designing a distributed estimation algorithm is substantially different from the centralized estimation problem.

Two critical aspects of the distributed estimation are (1) sharing and fusing state estimates among agents that are within same neighborhood and (2) updating the state estimate using the measurements on the system's state. In literature, the following class of parameterized linear estimation rules is proposed to implement the above two aspects in a single framework:

$$\begin{aligned} \dot{\hat{x}}_i(t) = & A\hat{x}_i(t) + Bu(t) \\ & + \underbrace{\sum_{j \in \mathbb{N}_i} \mathbf{H}_{ij} (\hat{x}_j(t) - \hat{x}_i(t))}_{\text{Estimate Fusion}} \\ & + \underbrace{\mathbf{K}_i (y_i(t) - C_i \hat{x}_i(t))}_{\text{Measurement Update}} + \mathbf{P}_i \underbrace{z_i(t)}_{\text{Augmented State}} \end{aligned} \quad (5a)$$

$$\dot{z}_i(t) = \mathbf{Q}_i (y_i(t) - C_i \hat{x}_i(t)) + \mathbf{S}_i z_i(t) \quad (5b)$$

We note that the third term in (5a) contributes to reaching agreement in the state estimates between neighboring agents and the fourth term is associated with the measurement update. The matrices $\mathbf{H}_{ij}$, $\mathbf{K}_i$, $\mathbf{P}_i$, $\mathbf{Q}_i$, $\mathbf{S}_i$ are the parameters of the estimation rule that need to be found in such a way that the estimate $\hat{x}_i(t)$ of every agent converges to the system's state $x(t)$ exponentially fast given that the disturbance terms $w_x(t)$ and $w_{y_i}(t)$ in (1) are both zero: for all i in $\{1, \dots, M\}$,

$$\|\hat{x}_i(t) - x(t)\|_2 \leq \alpha \exp(-\lambda t), \quad \forall t \geq 0 \quad (6)$$

where the positive variable λ is referred to as the *convergence rate*. We refer to such convergence of the state estimate at every agent as *state omniscience* (Park and Martins 2017).

The estimation rule (5) was motivated by the pioneering work (Olfati-Saber and Jalalkamali 2012) on distributed Kalman filtering (DKF) that proposed a new solution to the distributed estimation problem based on Kalman filtering and a consensus algorithm (Olfati-Saber et al. 2007). The major difference from the DKF approach is the introduction of the augmented states $z_i(t)$. The idea of having the augmented states was suggested in Park and Martins (2017) and Wang and Morse (2018) to establish a duality between the distributed estimation and decentralized control. In consequence, such duality allows to select suitable parameters of (5) that attain the state omniscience using decentralized controller synthesis methods. In the next section, we discuss more details on the parameter selection.

Parameter Selection for State Omniscience

One of the important design objectives is to select the parameters of the estimation rule (5) that result in the state omniscience. To achieve this objective, we first identify conditions on the system model (1) and the graph $\mathcal{G}$ that ensure the existence of such omniscience-achieving parameters, and then we devise a method to compute the parameters. We explain these two points based on recent results from Park and Martins (2017), Wang and Morse (2018), and Mitra and Sundaram (2018).

To explain this, let us recall a central property of (1) so-called *detectability*: the system model (1) is said to be detectable if the state $x(t)$ can be asymptotically estimated from $(y_1(\tau), \dots, y_M(\tau))$, $0 \leq \tau \leq t$ which are the measurements available to the entire network. As one can infer from the definition, the detectability is the minimum requirement for the system's state to be estimated using any type of estimation algorithms.

Park and Martins (2017) describe the necessary and sufficient conditions for the existence of an omniscience-achieving parameter selection in terms of the detectability of (1) and connectivity of the graph $\mathcal{G}$. In fact, when the graph is strongly connected, the detectability condition is the only requirement to ensure the existence of an omniscience-achieving parameter selection. In other cases, when the graph has multiple source components, a subsystem model of (1) associated with every source component needs to satisfy the detectability requirement.

Once the conditions are met, we can proceed with finding omniscience-achieving parameters for (5). In what follows, we discuss two representative approaches where, for the sake of the discussion, we assume that the graph $\mathcal{G}$ is strongly connected. The first approach is based on the results from Park and Martins (2017) and Wang and Morse (2018) in which the key idea is based on the observation that when (5) is re-written in terms of the estimation error $\tilde{x}_i(t) = \hat{x}_i(t) - x(t)$ and the augmented states $z_i(t)$, the parameter

selection problem can be equivalently viewed as a decentralized controller synthesis problem. By adopting well-established methods for decentralized control design (Corfmat and Morse 1976), one can find omniscience-achieving parameters for (5) for which the augmented state $z_1(k)$ of Agent 1 is required to be of the dimension $M - 1$ (the number of agents in the network less 1) and all other agents do not need to have the augmented states in their estimation rules. Hence, the average dimension of the estimation rule (5) becomes less than $n + 1$, which only increases linearly with respect to the order n of the system model. Furthermore, the method proposed in Wang and Morse (2018) explains how to select the parameters that attain a pre-selected convergence rate λ in (6).

The second approach is based on a canonical decomposition method from Mitra and Sundaram (2018). The parameter selection under this method is decomposed into the following two steps: Each agent i identifies a portion of the state $x(t)$ – called an *observable sub-state* of $x(t)$ – that can be estimated only from its own measurements $y_i(\tau)$, $0 \leq \tau \leq t$ and locally estimates the sub-state (without communication with other agents), using a centralized estimation approach such as the Luenberger observer. Then, through a consensus algorithm, the agent estimates the rest of $x(k)$. The method would have a limitation that each agent estimates its observable sub-state only with its own measurements, which would deteriorate the estimation quality when the measurements are subject to significant sensor noise $w_{y_i}(t)$. However, it has an advantage that all the agents in the network do not need to have the augmented states in their estimation rules, which reduces complexity in selecting the parameters for the estimation rule.

The above two approaches describe methods to select omniscience-achieving parameters for (5) when they exist. In addition to the parameter selection for the state omniscience, another critical design objective is in optimizing the parameter selection to improve disturbance attenuation performance of (5). In the next section, we review key contributions in the distributed estimation

study that describe methods to assess and optimize the performance.

Optimizing Disturbance Attenuation Performance

We discuss methods to analyze the effect of disturbances on performance of (5) and to refine

the parameter selection to attenuate such effect. Primary sources of the disturbances we consider are the modeling error $w_x(t)$ and sensor noise $w_{y_i}(t)$, and also we discuss cases in which the measurement matrix C_i and the neighborhood set $\mathbb{N}_i$ are subject to random switching. We begin by explaining the following two performance indices needed for our discussions:

$$\begin{aligned} H_\infty \text{ Estimation Performance} &= \frac{\text{Estimation Error}}{\text{Total Disturbance}} \\ &= \frac{(1/M) \sum_{i=1}^M \|\tilde{x}_i\|_{L_2}^2}{\|\tilde{x}(0)\|_2^2 + \|w_x\|_{L_2}^2 + (1/M) \sum_{i=1}^M \|w_{y_i}\|_{L_2}^2} \end{aligned} \quad (7)$$

$$\begin{aligned} H_\infty \text{ Consensus Performance} &= \frac{\text{Disagreement in State Estimates}}{\text{Total Disturbance}} \\ &= \frac{(1/M) \sum_{i=1}^M \sum_{j \in \mathbb{N}_i} \|\hat{x}_i - \hat{x}_j\|_{L_2}^2}{\|\tilde{x}(0)\|_2^2 + \|w_x\|_{L_2}^2 + (1/M) \sum_{i=1}^M \|w_{y_i}\|_{L_2}^2} \end{aligned} \quad (8)$$

where $\|\cdot\|_2$ is the 2-norm and for a given real-valued signal $a(t)$, $t \geq 0$, the norm $\|a\|_{L_2}$ is defined as $\|a\|_{L_2}^2 = \int_{t=0}^{\infty} \|a(t)\|_2^2 dt$. Essentially, the performance indices (7) and (8) describe the disturbance attenuation performance of (5) in attaining the state omniscience and reaching agreement (consensus) in state estimates, respectively, across the entire network, which are known as H_∞ robustness in estimation and consensus (Ugrinovskii 2011).

A practical consideration in the distributed estimation research is to devise computation methods for assessing and optimizing the performance indices (7) and (8). Theory on linear matrix inequality (LMI) has been widely adopted to assess disturbance attenuation performance of control and estimation algorithms. The theory uses matrix inequalities to characterize disturbance attenuation performance and also to design computational approaches to optimize the performance. In what follows, we introduce

some of key LMI-based approaches proposed in the distributed estimation literature.

Ugrinovskii (2011) proposes a LMI-based method to assess and optimize the performance indices (7) and (8) for the estimation rule (5). Notably, the method is used to establish a strong link between the H_∞ consensus performance and the parameter selection of $\mathbf{H}_{ij}$ in (5). The work of Ugrinovskii (2013) and Shen et al. (2010) investigates more challenging and practical scenarios in which the measurement matrix C_i and the neighborhood set $\mathbb{N}_i$ are subject to random switching. Such types of randomly switching measurement and communication models arise in engineering applications where sensors would fail to collect measurements and wireless communication becomes unreliable and suffers from random packet drops resulting in failure of information exchange between agents. Under this setting, LMI-based approaches are proposed in Ugrinovskii (2013) and Shen et al. (2010) to

analyze the effect of the sensor and communication failure on the H_∞ estimation and consensus performance, which also can be used to refine the parameter selection to attenuate the effect.

All these LMI-based approaches can be used not only to analyze and improve the disturbance attenuation performance but also as tools to design measurement models and communication topologies that attain desired performance.

Applications to Distributed Control

The theory of distributed estimation not only serves as principles in designing estimation algorithms in networks but also is applied to design control algorithms for large-scale dynamical systems in engineering applications. The work of Muehlebach and Trimpe (2018) investigates a problem of designing a communication-efficient distributed control algorithm for stabilizing a large-scale dynamical system. To achieve this, an event-triggered distributed estimation algorithm is proposed in which, based on devised event triggers, agents in a network selectively collect sensor measurements on the system's state and share the measurements across the entire network, which would be used to estimate and eventually stabilize the state of the system. Simulations with the proposed distributed control method demonstrate the possibility of using the method to safely maneuver a vehicle platoon while achieving communication efficiency.

The distributed estimation approach was adopted in developing animal-borne networked sensing devices (Park et al. 2019). The devices are designed to collect data on animal group behavior through registering their locations using GPS modules and recording animal point-of-view videos using on-board cameras. Since the video recording is an extremely power- and memory-intensive operation, prudent use of such data collection capability is needed to keep the devices running over an extended period of time. In this scenario, the distributed estimation is used to allow each animal-borne device to estimate the positions and velocities of members in an

animal group instrumented with the devices. The estimates on the group movement are then used to judiciously control the triggering of video recording to document group interactions among instrumented animals.

Summary and Future Directions

This entry overviews theory and application of distributed estimation in networks. The theory describes systematic ways to design a network of multiple agents that estimate the state of dynamical systems through sensing and communication. We reviewed key approaches that investigate the design of distributed estimation algorithms and study the conditions under which the algorithms attain the state omniscience. In addition, we discussed the disturbance attenuation performance of the algorithms and reviewed important LMI-based methods that characterize the performance and can be used to optimize the performance through parameter refinement.

Application is an important component of the distributed estimation research for which we have explained a few examples where the distributed estimation approaches are applied to control large-scale dynamical systems. Further investigations on algorithm design and applications to system control problems are important future directions which would include (1) co-designing distributed estimation and control algorithms for multi-agent decision-making over non-trivial communication graphs, which would change over time, and (2) investigating efficient inter-agent communication schemes for the distributed estimation that find the optimal trade-off between power consumption due to the communication and the estimation performance.

Distributed Model Predictive Control

Gabriele Pannocchia
University of Pisa, Pisa, Italy

Abstract

Distributed model predictive control refers to a class of predictive control architectures in which a number of local controllers manipulate a subset of inputs to control a subset of outputs (states) composing the overall system. Different levels of communication and (non)cooperation exist, although in general the most compelling properties can be established only for cooperative schemes, those in which all local controllers optimize local inputs to minimize the same plantwide objective function. Starting from state-feedback algorithms for constrained linear systems, extensions are discussed to cover output feedback, reference target tracking, and nonlinear systems. An outlook of future directions is finally presented.

Keywords

Constrained large-scale systems · Cooperative control systems · Interacting dynamical systems

Introduction and Motivations

Large-scale systems (e.g., industrial processing plants, power generation networks, etc.) usually comprise several interconnected units which may exchange material, energy, and information streams. The overall effectiveness and profitability of such large-scale systems depend strongly on the level of local effectiveness and profitability of each unit but also on the level of interactions among the different units. An overall optimization goal can be achieved by adopting a single *centralized* model predictive control (MPC) system (Rawlings et al. 2017) in which *all* control input trajectories are optimized simultaneously to minimize a *common* objective.

This choice is often avoided for several reasons. When the overall number of inputs and states is very large, a single optimization problem may require computational resources (CPU time, memory, etc.) that are not available and/or compatible with the system's dynamics. Even if these limitations do not hold, it is often the case that organizational reasons require the use of smaller, local controllers, which are easier to coordinate and maintain.

Thus, industrial control systems are often *decentralized*, i.e., the overall system is divided into (possibly mildly coupled) subsystems, and a local controller is designed for each unit disregarding the interactions from/to other subsystems. Depending on the extent of dynamic coupling, it is well-known that the performance of such decentralized systems may be poor and stability properties may be even lost. *Distributed* predictive control architectures arise to meet performance specifications (stability at minimum) similar to centralized predictive control systems, still retaining the modularity and local character of the optimization problems solved by each controller.

Definitions and Architectures for Constrained Linear Systems

Subsystem Dynamics, Constraints, and Objectives

We start the description of distributed MPC algorithms by considering an overall discrete-time linear time-invariant system in the form:

$$x^+ = Ax + Bu, \quad y = Cx \quad (1)$$

in which $x \in \mathbb{R}^n$ and $x^+ \in \mathbb{R}^n$ are, respectively, the system state at a given time and, at a successor time, $u \in \mathbb{R}^m$ is the input and $y \in \mathbb{R}^p$ is the output.

We consider that the overall system (1) is divided into M subsystems, $\mathbb{S}_i$, defined by (dis-joint) sets of inputs and outputs (states), and each $\mathbb{S}_i$ is regulated by a *local* MPC. For each $\mathbb{S}_i$, we denote by $y_i \in \mathbb{R}^{p_i}$ its output, by $x_i \in \mathbb{R}^{n_i}$ its state, and by $u_i \in \mathbb{R}^{m_i}$ the control input

computed by the i th MPC. Due to interactions among subsystems, the local output y_i (and state x_i) is affected by control inputs computed by (some) other MPCs. Hence, the dynamics of $\mathbb{S}_i$ can be written as

$$x_i^+ = A_i x_i + B_i u_i + \sum_{j \in \mathcal{N}_i} B_{ij} u_j, \quad y_i = C_i x_i \quad (2)$$

in which $\mathcal{N}_i$ denotes the indices of *neighbors* of $\mathbb{S}_i$, i.e., the subsystems whose inputs have an influence on the states of $\mathbb{S}_i$. To clarify the notation, we depict in Fig. 1 the case of three subsystems, with neighbors $\mathcal{N}_1 = \{2, 3\}$, $\mathcal{N}_2 = \{1\}$, and $\mathcal{N}_3 = \{2\}$.

Without loss of generality, we assume that each pair (A_i, B_i) is stabilizable. Moreover, the state of each subsystem x_i is assumed known (to the i th MPC) at each decision time. For each subsystem $\mathbb{S}_i$, inputs are required to fulfill (hard) constraints:

$$u_i \in \mathbb{U}_i, \quad i = 1, \dots, M \quad (3)$$

in which $\mathbb{U}_i$ are polyhedrons containing the origin in their interior. Moreover, we consider a quadratic stage cost function $\ell_i(x, u) \triangleq \frac{1}{2}(x' Q_i x + u' R_i u)$ and a terminal cost function $V_{fi}(x) \triangleq \frac{1}{2}x' P_i x$, with $Q_i \in \mathbb{R}^{n_i \times n_i}$, $R_i \in \mathbb{R}^{m_i \times m_i}$, and $P_i \in \mathbb{R}^{n_i \times n_i}$ positive definite.

Distributed Model Predictive Control, Fig. 1
Interconnected systems and neighbors definition

Without loss of generality, let $x_i(0)$ be the state of S_i at the current decision time. Consequently, the finite-horizon cost function associated with S_i is given by:

$$V_i(x_i(0), \mathbf{u}_i, \{\mathbf{u}_j\}_{j \in \mathcal{N}_i}) \triangleq \sum_{k=0}^{N-1} \ell_i(x_i(k), u_i(k)) + V_{fi}(x_i(N)) \quad (4)$$

in which $\mathbf{u}_i = (u_i(0), u_i(1), \dots, u_i(N-1))$ is a finite-horizon sequence of control inputs of S_i and $\mathbf{u}_j$ is similarly defined as a sequence of control inputs of each neighbor $j \in \mathcal{N}_i$. Notice that $V_i(\cdot)$ is a function of neighbors' input sequences, $\{\mathbf{u}_j\}_{j \in \mathcal{N}_i}$, due to the dynamics (2).

Decentralized, Noncooperative, and Cooperative Predictive Control Architectures

Several levels of communications and (non)cooperation can exist among the controllers, as depicted in Fig. 2 for the case of two subsystems.

In *decentralized* MPC architectures, interactions among subsystems are neglected by forcing $\mathcal{N}_i = \emptyset$ for all i even if this is not true. That is, the subsystem model used in each local controller, instead of (2), is simply

$$x_i^+ = A_i x_i + B_i u_i, \quad y_i = C_i x_i \quad (5)$$

Therefore, an inherent mismatch exists between the model used by the local controllers (5) and the actual subsystem dynamics (2). Each local MPC solves the following finite-horizon optimal control problem (FHOCP):

$$\mathbb{P}_i^{\text{De}} : \min_{\mathbf{u}_i} V_i(\cdot) \quad \text{s.t. } \mathbf{u}_i \in \mathbb{U}_i^N, \mathcal{N}_i = \emptyset \quad (6)$$

We observe that in this case, $V_i(\cdot)$ depends only on local inputs, $\mathbf{u}_i$, because it is assumed that $\mathcal{N}_i = \emptyset$. Hence, each $\mathbb{P}_i^{\text{De}}$ is solved independently of the neighbors computations, and no iterations are performed. Clearly, depending on the actual level of interactions among subsystems, decentralized MPC architectures can perform poorly, namely,

Distributed Model Predictive Control, Fig. 2 Three distributed control architectures: decentralized MPC, noncooperative MPC, and cooperative MPC

being non-stabilizing. Performance certifications are still possible resorting to robust stability theory, i.e., by treating the neglected dynamics $\sum_{j \in \mathcal{N}_i} B_{ij} u_j$ as (bounded) disturbances (Riverso et al. 2013).

In *noncooperative* MPC architectures, the existing interactions among the subsystems are fully taken into account through (2). Given a known value of the neighbors' control input sequences, $\{\mathbf{u}_j\}_{j \in \mathcal{N}_i}$, each local MPC solves the following FHOC:

$$\mathbb{P}_i^{\text{NCDi}} : \min_{\mathbf{u}_i} V_i(\cdot) \text{ s.t. } \mathbf{u}_i \in \mathbb{U}_i^N \quad (7)$$

The obtained solution can be exchanged with the other local controllers to update the assumed neighbors' control input sequences, and iterations can be performed. We observe that this approach is noncooperative because local controllers try to optimize different, possibly competing, objectives. In general, no convergence is guaranteed in noncooperative iterations, and when this scheme converges, it leads to a so-called Nash equilibrium. However, the achieved local control inputs do not have proven stability properties (Rawlings et al. 2017, §6.2.3). To ensure closed-loop stability, variants can be formulated by including a sequential solution of local MPC problems; exploiting the notion (if any) of an auxiliary stabilizing decentralized control law, non-iterative noncooperative schemes are also proposed, in which stability guarantees are provided by ensuring a decrease of a centralized Lyapunov function at each decision time.

Finally, in *cooperative* MPC architectures, each local controller optimizes a common (plantwide) objective:

$$V(x(0), \mathbf{u}) \triangleq \sum_{i=1}^M \rho_i V_i(x_i(0), \mathbf{u}_i, \{\mathbf{u}_j\}_{j \in \mathcal{N}_i}) \quad (8)$$

in which $\rho_i > 0$, for all i , are given scalar weights and $\mathbf{u} \triangleq (\mathbf{u}_1, \dots, \mathbf{u}_M)$ is the overall control sequence. In particular, given a known value of other subsystems' control input sequences, $\{\mathbf{u}_j\}_{j \neq i}$, each local MPC solves the following FHOC:

$$\mathbb{P}_i^{\text{CDi}} : \min_{\mathbf{u}_i} V(\cdot) \text{ s.t. } \mathbf{u}_i \in \mathbb{U}_i^N \quad (9)$$

As in noncooperative schemes, the obtained solution can be exchanged with the other local controllers, and further iterations can be performed. Notice that in $\mathbb{P}_i^{\text{CDi}}$, the (possible) implications of the local control sequence $\mathbf{u}_i$ to all other subsystems' objectives, $V_j(\cdot)$ with $j \neq i$, are taken into account, as well as the effect of the neighbors' sequences $\{\mathbf{u}_j\}_{j \in \mathcal{N}_i}$ on the local state evolution through (2). Clearly, this approach is termed cooperative because all controllers compute *local* inputs to minimize a *global* objective. Convergence of cooperative iterations is guaranteed, and under suitable assumptions the converged solution is the centralized Pareto-optimal solution (Rawlings et al. 2017, §6.2.4). Furthermore, the achieved local control inputs have proven stabilizing properties (Stewart et al. 2010). Variants are also proposed in which each controller still optimizes a local objective, but cooperative iterations are performed to ensure a decrease of the global objective at each decision time (Maestre et al. 2011).

Cooperative Distributed MPC

Cooperative schemes are preferable over noncooperative schemes from many points of view, namely, in terms of superior theoretical guarantees and no larger computational requirements. In this section we focus on a prototype cooperative distributed MPC algorithm adapted from Stewart et al. (2010), highlighting the required computations and discussing the associated theoretical properties and guarantees.

Basic Algorithm

We present in Algorithm 1 a streamlined description of a cooperative distributed MPC algorithm, in which each local controller solves $\mathbb{P}_i^{\text{CDi}}$, given a previously computed value of all other subsystems' input sequences. For each local controller, the new iterate is defined as a convex combination of the newly computed solution with the previous iteration. A relative tolerance is defined, so that

cooperative iterations stop when all local controllers have computed a new iterate sufficiently close to the previous one. A maximum number of cooperative iterations can also be defined, so that a finite bound on the execution time can be established.

Algorithm 1 (*Cooperative MPC*). **Require:**

Overall warm start $\mathbf{u}^0 \triangleq (\mathbf{u}_1^0, \dots, \mathbf{u}_M^0)$, convex step weights $w_i > 0$, s.t. $\sum_{i=1}^M w_i = 1$, relative tolerance parameter $\epsilon > 0$, maximum cooperative iterations $c_{\max}$

```

1: Initialize:  $c \leftarrow 0$  and  $e_i \leftarrow 2\epsilon$  for  $i = 1, \dots, M$ .
2: while ( $c < c_{\max}$ ) and ( $\exists i | e_i > \epsilon$ ) do
3:    $c \leftarrow c + 1$ .
4:   for  $i = 1$  to  $M$  do
5:     Solve  $\mathbb{P}_i^{\text{CDi}}$  in (9) obtaining  $\mathbf{u}_i^*$ .
6:   end for
7:   for  $i = 1$  to  $M$  do
8:     Define new iterate:  $\mathbf{u}_i^c \triangleq w_i \mathbf{u}_i^* + (1 - w_i) \mathbf{u}_i^{c-1}$ .
9:     Compute convergence error:  $e_i \triangleq \frac{\|\mathbf{u}_i^c - \mathbf{u}_i^{c-1}\|}{\|\mathbf{u}_i^{c-1}\|}$ .
10:  end for
11: end while
12: return Overall solution:  $\mathbf{u}^c \triangleq (\mathbf{u}_1^c, \dots, \mathbf{u}_M^c)$ .

```

We observe that Step 8 implicitly defines the new overall iterate as a convex combination of the overall solutions *achieved* by each controller, that is,

$$\mathbf{u}^c = \sum_{i=1}^M w_i (\mathbf{u}_1^{c-1}, \dots, \mathbf{u}_i^*, \dots, \mathbf{u}_M^{c-1}) \quad (10)$$

It is also important to observe that Steps 5, 8, and 9 are performed separately by each controller.

Properties

The basic cooperative MPC described in Algorithm 1 enjoys several nice theoretical and practical properties, as detailed (Rawlings et al. 2017, §6.3.1):

1. *Feasibility of each iterate:* $\mathbf{u}_i^{c-1} \in \mathbb{U}_i^N$ implies $\mathbf{u}_i^c \in \mathbb{U}_i^N$, for all $i = 1, \dots, M$ and $c \in \mathbb{I}_{>0}$.
2. *Cost decrease at each iteration:* $V(x(0), \mathbf{u}^c) \leq V(x(0), \mathbf{u}^{c-1})$ for all $c \in \mathbb{I}_{>0}$.

3. *Cost convergence to the centralized optimum:* $\lim_{c \rightarrow \infty} V(x(0), \mathbf{u}^c) = \min_{\mathbf{u} \in \mathbb{U}^N} V(x(0), \mathbf{u})$, in which $\mathbb{U} \triangleq \mathbb{U}_1 \times \dots \times \mathbb{U}_M$.

Resorting to suboptimal MPC theory, the above properties (1) and (2) can be exploited to show that the origin of closed-loop system

$$x^+ = Ax + B\kappa^c(x), \text{ with } \kappa^c(x) \triangleq \mathbf{u}^c(0) \quad (11)$$

is *exponentially stable* for any finite $c \in \mathbb{I}_{>0}$. This result is of paramount (practical and theoretical) importance because it ensures closed-loop stability using cooperative distributed MPC with any finite number of cooperative iterations. As in centralized MPC based on the solution of a FHOC (Rawlings et al. 2017, §2.4.2), particular care of the terminal cost function $V_{fi}(\cdot)$ is necessary, possibly in conjunction with a terminal constraint $x_i(N) \in \mathbb{X}_{fi}$. Several options can be adopted as discussed, e.g., in Stewart et al. (2010, 2011).

Moreover, the results in Pannocchia et al. (2011) can be used to show *inherent robust stability* to system's disturbances and measurement errors. Therefore, we can confidently state that well-designed distributed cooperative MPC and centralized MPC algorithms share the *same guarantees* in terms of stability and robustness.

Complementary Aspects

We discuss in this section a number of complementary aspects of distributed MPC algorithms, omitting technical details for the sake of space.

Coupled Input Constraints and State Constraints

Convergence of the solution of cooperative distributed MPC toward the centralized (global) optimum holds when input constraints are in the form of (3), i.e., when no constraints involve inputs of different subsystems. Sometimes this assumption fails to hold, e.g., when several units share a common utility resource, that is, in addition to (3) some constraints involve inputs of more than one unit. In this situation, it is possible

that Algorithm 1 remains stuck at a fixed point, without improving the cost, even if it is still away from the centralized optimum (Rawlings et al. 2017, §6.3.2). It is important to point out that this situation is harmless from a closed-loop stability and robustness point of view. However, the degree of suboptimality in comparison with centralized MPC could be undesired from a performance point of view. To overcome this situation, a slightly different partitioning of the overall inputs into non-disjoint sets can be adopted (Stewart et al. 2010).

Similarly the presence of state constraints, even in decentralized form $x_i \in \mathbb{X}_i$ (with $i = 1, \dots, M$), can prevent convergence of a cooperative algorithm toward the centralized optimum. It is also important to point out that the local MPC controlling $\mathbb{S}_i$ needs to consider in the optimal control problem, besides local state constraints $x_i \in \mathbb{X}_i$ and also state constraints of all other subsystems $\mathbb{S}_j$ such that $i \in \mathcal{N}_j$. This ensures feasibility of each iterate and cost reduction; hence closed-loop stability (and robustness) can be established.

Another route to address the presence of coupling constraints is that based on suitable decomposition methods for distributed optimization, such as the dual decomposition and alternative direction method of multipliers (Doan et al. 2011; Farokhi et al. 2014).

Parsimonious Local System Representations

In cooperative distributed algorithms, each local optimization problem (9) is solved considering the evolution of the overall system state over the prediction horizon, so that the centralized cost function can be optimized by each local controller. Depending on the interconnections among the subsystems, this approach could be simplified by considering a subset of overall state dynamics, without losing the global optimality guarantees, as proposed in Razzanelli and Pannocchia (2017) and briefly reviewed.

From graph theory, we define the *outlet star* of each local subsystem $\mathbb{S}_i$, as the set of subsystems $\mathbb{S}_j$ of which $\mathbb{S}_i$ is neighbor, i.e., $\mathcal{O}_i = \{j | i \in \mathcal{N}_j\}$. Thus, the augmented state dynamics that should

be considered by $\mathbb{S}_i$ is composed by (2) and

$$\begin{aligned} x_j^+ &= A_j x_j + B_{ji} u_i + B_j u_j + \sum_{k \in \mathcal{N}_j \setminus i} B_{jk} u_k, \\ y_j &= C_j x_j \quad \forall j \in \mathcal{O}_i \end{aligned} \quad (12)$$

Thus, the FHOC (9) can be simplified to the following, more parsimonious, problem:

$$\mathbb{P}_i^{\text{PaCDi}} : \min_{\mathbf{u}_i} V_i(\cdot) + \sum_{j \in \mathcal{O}_i} V_j(\cdot) \quad \text{s.t. } \mathbf{u}_i \in \mathbb{U}_i^N \quad (13)$$

obtaining the same solution with significant computational savings (Razzanelli and Pannocchia 2017).

Output Feedback and Offset-Free Tracking

When the subsystem state cannot be directly measured, each local controller can use a local state estimator, namely, a Kalman filter (or Luenberger observer). Assuming that the pair (A_i, C_i) is detectable, the subsystem state estimate evolves as follows:

$$\hat{x}_i^+ = A_i \hat{x}_i + B_i u_i + \sum_{j \in \mathcal{N}_i} B_{ij} u_j + L_i (y_i - C_i \hat{x}_i) \quad (14)$$

in which $L_i \in \mathbb{R}^{n_i \times p_i}$ is the local Kalman predictor gain, chosen such that the matrix $(A_i - L_i C_i)$ is Schur. Stability of the closed-loop origin can be still established using minor variations (Rawlings et al. 2017, §6.3.3).

When offset-free control is sought, each local MPC can be equipped with an integrating disturbance model similarly to centralized offset-free MPC algorithms (Pannocchia 2015). Given the current estimate of the subsystem state and disturbance, a target calculation problem is solved to compute the state and input equilibrium pair such that (a subset of) output variables correspond to given set points. Such a target calculation problem can be performed in a centralized fashion or in a distributed manner (Razzanelli and Pannocchia 2017). Furthermore, the target calculation problem can be embedded into the FHOC (Ferramosca et al. 2013; Razzanelli and Pannocchia 2017).

Distributed Control for Nonlinear Systems

Several nonlinear distributed MPC algorithms have been recently proposed (Liu et al. 2009; Stewart et al. 2011). Some schemes require the presence of a coordinator, thus introducing a hierarchical structure (Scattolini 2009). In Stewart et al. (2011), instead, a cooperative distributed MPC architecture similar to the one discussed in the previous section has been proposed for nonlinear systems. Each local controller considers the following subsystem model:

$$\begin{aligned} x_i^+ &= f_i(x_i, u_i, u_j), \quad \text{with } j \in \mathcal{N}_i \\ y_i &= h_i(x_i) \end{aligned} \quad (15)$$

A problem (formally) identical to $\mathbb{P}_i^{\text{CDi}}$ in (9) is solved by each controller, and cooperative iterations are performed. However, non-convexity of $\mathbb{P}_i^{\text{CDi}}$ can make a convex combination step similar to Step 8 in Algorithm 1 not necessarily a cost improvement. As a workaround in such cases, Stewart et al. (2011) propose deleting the least effective control sequence computed by a local controller (repeating this deletion if necessary). In this way it is possible to show a monotonic decrease of the cost function at each cooperative iteration (Rawlings et al. 2017, §6.5).

Summary and Future Directions

We presented the basics and foundations of distributed model predictive control (DMPC) schemes, which prove useful and effective in the control of large-scale systems for which a single centralized predictive controller is not regarded as a possible or desirable solution, e.g., due to organizational requirements and/or computational limitations. In DMPCs, the overall controlled system is organized into a number of subsystems, in general featuring some dynamic couplings, and for each subsystem a local MPC is implemented.

Different flavors of communication and cooperation among the local controllers can be chosen by the designer, ranging from *decentralized* to

cooperative schemes. In cooperative DMPC algorithms, the dynamic interactions among the subsystems are fully taken into account, with limited communication overheads, and the same overall objective can be optimized by each local controller. When cooperative iterations are performed upon convergence, such DMPC algorithms achieve the same global minimum control sequence as that of the centralized MPC. Termination prior to convergence does not hinder stability and robustness guarantees.

In this contribution, after discussing an overview on possible communication and cooperation schemes, we addressed the design of a state-feedback and distributed MPC algorithm for linear systems subject to input constraints, with convergence and stability guarantees. Then, we discussed various extensions to coupled input constraints and state constraints, output feedback, reference target tracking, and nonlinear systems.

The research on DMPC algorithms has been extensive during the last decade, and some excellent review papers have been recently made available (Christofides et al. 2013; Scattolini 2009). Still, we expect DMPC to attract research efforts in various directions, as briefly discussed:

- *Nonlinear DMPC* algorithms (Liu et al. 2009; Stewart et al. 2011; Hours and Jones 2015) will require improvements in terms of global optimum goals.
- *Economic DMPC* and *tracking DMPC* (Ferramosca et al. 2013; Razzanelli and Pannocchia 2017; Köhler et al. 2018) will replace current formulations designed for regulation around the origin.
- *Reconfigurability*, e.g., addition/deletion of new local subsystems and controllers, is an ongoing topic, which finds particular applicability in the context of smart-grid systems (Molzahn et al. 2017). Preliminary results, discussed in Rivero et al. (2013) for decentralized control structures, have been also extended to distributed nonlinear systems (Rivero et al. 2016).

- *Constrained distributed estimation*, preliminarily addressed in Farina et al. (2012), is drawing attention (Yin and Liu 2017), although further insights are needed to bridge the gap between constrained estimation and control algorithms.
- Specific *distributed optimization algorithms* tailored to DMPC problems (Doan et al. 2011; Farokhi et al. 2014; Molzahn et al. 2017) will increase the effectiveness of DMPC algorithms.

Abstract

The paper provides an overview of the distributed first-order optimization methods for solving a constrained convex minimization problem, where the objective function is the sum of local objective functions of the agents in a network. This problem has gained a lot of interest due to its emergence in many applications in distributed control and coordination of autonomous agents and distributed estimation and signal processing in wireless networks.

method · Networked systems

Introduction

There has been much recent interest in distributed optimization pertinent to optimization aspects arising in control and coordination of networks consisting of multiple (possibly mobile) agents and in estimation and signal processing in sensor networks (Mesbahi and Egerstedt 2010; Bullo et al. 2009; Hendrickx 2008; Olshevsky 2010; Kar and Moura 2011; Martinoli et al. 2013). In many of these applications, the network system goal is to optimize a global objective through local agent-based computations and local information exchange with immediate neighbors in the underlying communication network. This is motivated mainly by the emergence of large-scale data and/or large-scale networks and new networking applications such as mobile ad hoc networks and wireless sensor networks, characterized by the lack of centralized access to information and time-varying connectivity.

Control and optimization algorithms deployed in such networks should be completely distributed (relying only on local observations and information), robust against unexpected changes in topology (i.e., link or node failures) and against unreliable communication (noisy links or quantized data) (see ► [Networked Systems](#)). Furthermore, it is desired that the algorithms are scalable in the size of the network.

Generally speaking, the problem of distributed optimization consists of three main components:

1. The optimization problem that the network of agents wants to solve collectively (specifying an objective function and constraints)
2. The local information structure, which describes what information is locally known or observable by each agent in the system (who knows what and when)
3. The communication structure, which specifies the connectivity topology of the underlying communication network and other features of the communication environment

The algorithms for solving such global network problems need to comply with the distributed knowledge about the problem among the agents and obey the local connectivity structure of the communication network (► [Networked Systems](#); ► [Graphs for Modeling Networked Interactions](#)).

Networked System Problem

Given a set $N = \{1, 2, \dots, n\}$ of agents (also referred to as nodes), the global system problem has the following form:

$$\begin{aligned} &\text{minimize} && \sum_{i=1}^n f_i(x) \\ &\text{subject to} && x \in X. \end{aligned} \quad (1)$$

Each $f_i : \mathbb{R}^d \rightarrow \mathbb{R}$ is a convex function which represents the local objective of agent i , while $X \subseteq \mathbb{R}^d$ is a closed convex set. The function f_i is a private function known only to agent i ,

while the set X is commonly known by all agents $i \in N$. The vector $x \in X$ represents a global decision vector which the agents want to optimize using local information. The problem is a simple constrained convex optimization problem, where the global objective function is given by the sum of the individual objective functions $f_i(x)$ of the agents in the system. As such, the objective function is the sum of non-separable convex functions corresponding to multiple agents connected over a network.

As an example, consider the problem arising in support vector machines (SVMs), which are a popular tool for classification problems. Each agent i has a set $S_i = \left\{ \left(a_j^{(i)}, b_j^{(i)} \right) \right\}_{j=1}^{m_i}$ of m_i sample-label pairs, where $a_j^{(i)} \in \mathbb{R}^d$ is a data point and $b_j^{(i)} \in \{+1, -1\}$ is its corresponding (correct) label. The number m_i of data points for every agent i is typically very large (hundreds of thousands). Without sharing the data points, the agents want to collectively find a hyperplane that separates all the data, i.e., a hyperplane that separates (with a maximal separation distance) the data with label 1 from the data with label -1 in the global data set $\bigcup_{i=1}^n S_i$. Thus, the agents need to solve an unconstrained version of the problem (1), where the decision variable $x \in \mathbb{R}^d$ is a hyperplane normal and the objective function f_i of agent i is given by

$$f_i(x) = \frac{\lambda}{2} \|x\|^2 + \sum_{j=1}^{m_i} \max \left\{ 0, 1 - b_j^{(i)} \left(x' a_j^{(i)} \right) \right\},$$

where λ is a regularization parameter (common to all agents).

The network communication structure is represented by a directed (or undirected) graph $G = (N, E)$, with the vertex set N and the edge set E . The network is used as a medium to diffuse the information from an agent to every other agent through local agent interactions over time ([► Graphs for Modeling Networked Interactions](#)). To accommodate the information spread through the entire network, it is typically assumed that the network communication graph $G = (N, E)$ is strongly connected

([► Dynamic Graphs, Connectivity of](#)). In the graph, a link (i, j) means that agent $i \in N$ receives the relevant information from agent $j \in N$.

Distributed Algorithms

The algorithms for solving problem (1) are constructed by using standard optimization techniques in combination with a mechanism for information diffusion through local agent interactions. A control point of view for the design of distributed algorithms has a nice exposition in Wang and Elia (2011).

One of the existing optimization techniques is the so-called incremental method, where the information is processed along a directed cycle in the graph. In this approach the estimate is passed from an agent to its neighbor (along the cycle), and only one agent updates at a time (Bertsekas 1997; Tseng 1998; Nedić and Bertsekas 2000, 2001; Nedić et al. 2001; Rabbat and Nowak 2004; Johansson et al. 2009; Blatt et al. 2007; Ram et al. 2009; Johansson 2008); for a detailed literature on incremental methods, see the textbooks Bertsekas (1999) and Bertsekas et al. (2003).

More recently, one of the techniques that gained popularity as a mechanism for information diffusion is a consensus protocol, in which the agent diffuses the information through the network through locally weighted averaging of their incoming data ([► Averaging Algorithms and Consensus](#)). The problem of reaching a consensus on a particular scalar value, or computing exact averages of the initial values of the agents, has gained an unprecedented interest as a central problem inherent to cooperative behavior in networked systems (Olshevsky 2010; Vicsek et al. 1995; Jadbabaie et al. 2003; Boyd et al. 2005; Olfati-Saber and Murray 2004; Cao et al. 2005, 2008a,b; Olshevsky and Tsitsiklis 2006, 2009; Wan and Lemmon 2009; Blondel et al. 2005; Touri 2011).

Using the consensus technique, a class of distributed algorithms has emerged, as a combination of the consensus protocols and the gradient-type methods. The gradient-based

approaches are particularly suitable, as they have a small overhead per iteration and are, in general, robust to various sources of errors and uncertainties.

The technique of using the network as a medium to propagate the relevant information for optimization purpose has its origins in the work by Tsitsiklis (1984), Tsitsiklis et al. (1986), and Bertsekas and Tsitsiklis (1997), where the network has been used to decompose the vector x components across different agents, while all agents share the same objective function.

Algorithms Using Weighted Averaging

The technique has recently been employed in Nedić and Ozdaglar (2009) (see also Nedić and Ozdaglar 2007, 2010) to deal with problems of the form (1) when the agents have different objective functions f_i , but their decisions are fully coupled through the common vector variable x . In a series of recent work (to be detailed later), the following distributed algorithm has emerged. Letting $x_i(k) \in X$ be an estimate (of the optimal decision) at agent i and time k , the next iterate is constructed through two updates. The first update is a consensus-like iteration, whereby, upon receiving the estimates $x_j(k)$ from its (in)neighbors j , the agent i aligns its estimate with its neighbors through averaging, formally given by

$$v_i(k) = \sum_{j \in N_i} w_{ij} x_j(k), \quad (2)$$

where N_i is the neighbor set

$$N_i = \{j \in N | (j, i) \in E\} \cup \{i\}.$$

The neighbor set N_i includes agent i itself, since the agent always has access to its own information. The scalar w_{ij} is a nonnegative weight that agent i places on the incoming information from neighbor $j \in N_i$. These weights sum to 1, i.e., $\sum_{j \in N_i} w_{ij} = 1$, thus yielding $v_i(k)$ as a (local) convex combination of $x_j(k)$, $j \in N_i$, obtained by agent i .

After computing $v_i(k)$, agent i computes a new iterate $x_i(k+1)$ by performing a gradient-

projection step, aimed at minimizing its own objective f_i , of the following form:

$$x_i(k+1) = \Pi_X [v_i(k) - \alpha(k) \nabla f_i(v_i(k))], \quad (3)$$

where $\Pi_X[x]$ is the projection of a point x on the set X (in the Euclidean norm), $\alpha(k) > 0$ is the stepsize at time k , and $\nabla f_i(z)$ is the gradient of f_i at a point z .

When all functions are zero and X is the entire space $\mathbb{P}^d$, the distributed algorithm (2) and (3) reduces to the linear-iteration method:

$$x_i(k+1) = \sum_{j \in N_i} w_{ij} x_j(k), \quad (4)$$

which is known as *consensus* or *agreement protocol*. This protocol is employed when the agents in the network wish to align their decision vectors $x_i(k)$ to a common vector $\hat{x}$. The alignment is attained asymptotically (as $k \rightarrow \infty$).

In the presence of objective function and constraints, the distributed algorithm in (2) and (3) corresponds to “forced alignment” guided by the gradient forces $\sum_{i=1}^n \nabla f_i(x)$. Under appropriate conditions, the alignment is forced to a common vector x^* that minimizes the network objective $\sum_{i=1}^n f_i(x)$ over the set X . This corresponds to the convergence of the iterates $x_i(k)$ to a common solution $x^* \in X$ as $k \rightarrow \infty$ for all agents $i \in N$.

The conditions under which the convergence of $\{x_i(k)\}$ to a common solution $x^* \in X$ occurs are a combination of the conditions needed for the consensus protocol to converge and the conditions imposed on the functions f_i and the stepsize $\alpha(k)$ to ensure the convergence of standard gradient-projection methods. For the consensus part, the conditions should guarantee that the pure consensus protocol in (4) converges to the average $\frac{1}{n} \sum_{i=1}^n x_i(0)$ of the initial agent values. This requirement transfers to the condition that the weights w_{ij} give rise to a doubly stochastic weight matrix W , whose entries are w_{ij} defined by the weights in (4) and augmented by $w_{ij} = 0$ for $j \notin N_i$.

Intuitively, the requirement that the weight matrix W is doubly stochastic ensures that each

agent has the same influence on the system behavior, in a long run. More specifically, the doubly stochastic weights ensure that the system as whole minimizes $\sum_{i=1}^n \frac{1}{n} f_i(x)$, where the factor $1/n$ is seen as portion of the influence of agent i . When the weight matrix W is only row stochastic, the consensus protocol converges to a weighted average $\sum_{i=1}^n \pi_i x_i(0)$ of the agent initial values, where π is the left eigenvector of W associated with the eigenvalue 1. In general, the values π_i can be different for different indices i , and the distributed algorithm in (2) and (3) results in minimizing the function $\sum_{i=1}^n \pi_i f_i(x)$ over X , and thus not solving problem (1).

The distributed algorithm (2) and (3) has been proposed and analyzed in Ram et al. (2010a, 2012), where the convergence had been established for diminishing stepsize rule (i.e., $\sum_k \alpha(k) = \infty$ and $\sum_k \alpha^2(k) < \infty$). As seen from the convergence analysis (see, e.g., Nedić and Ozdaglar 2009; Ram et al. 2012), for the convergence of the method, it is critical that the iterate disagreements $\|x_i(k) - x_j(k)\|$ converge linearly in time, for all $i \neq j$. This fast disagreement decay seems to be indispensable for ensuring the stability of the iterative process (2) and (3).

According to the distributed algorithm (2) and (3), at first, each agent aligns its estimate $x_i(k)$ with the estimates $x_j(k)$ that are received from its neighbors and, then, updates based on its local objective f_i which is to be minimized over $x \in X$. Alternatively, the distributed method can be constructed by interchanging the alignment step and the gradient-projection step. Such a method, while having the same asymptotic performance as the method in (2) and (3), exhibits a somewhat slower (transient) convergence behavior due to a larger misalignment resulting from taking the gradient-based updates at first. This alternative has been initially proposed independently in Lopes and Sayed (2006) (where simulation results have been reported), in Nedić and Ozdaglar (2007, 2009) (where the convergence analysis for a time-varying networks and a constant stepsize is given), and in Nedić et al. (2008) (with the quantization effects) and further investigated in Lopes and Sayed (2008), Nedić

et al. (2010), and Cattivelli and Sayed (2010). More recently, it has been considered in Lobel et al. (2011) for state-dependent weights and in Tu and Sayed (2012) where the performance is compared with that of an algorithm of the form (2) and (3) for estimation problems.

Algorithm Extensions: Over the past years, many extensions of the distributed algorithm in (2) and (3) have been developed, including the following:

- (a) *Time-varying communication graphs:* The algorithm naturally extends to the case of time-varying connectivity graphs $\{G(k)\}$, with $G(k) = (N, E(k))$ defined over the node set N and time-varying links $E(k)$. In this case, the weights w_{ij} in (2) are replaced with $w_{ij}(k)$ and, similarly, the neighbor set N_i is replaced with the corresponding time-dependent neighbor set $N_i(k)$ specified by the graph $G(k)$. The convergence of the algorithm (2) and (3) with these modifications typically requires some additional assumptions of the network connectivity over time and the assumptions on the entries in the corresponding weight matrix sequence $\{W(k)\}$, where $w_{ij}(k) = 0$ for $j \notin N_i(k)$. These conditions are the same as those that guarantee the convergence of the (row stochastic) matrix sequence $\{W(k)\}$ to a rank-one row-stochastic matrix, such as a connectivity over some fixed period (of a sliding-time window), the nonzero diagonal entries in $W(k)$, and the existence of a uniform lower bound on positive entries in $W(k)$; see, for example, Cao et al. (2008b), Touri (2011), Tsitsiklis (1984), Nedić and Ozdaglar (2010), Moreau (2005), and Ren and Beard (2005).
- (b) *Noisy gradients:* The algorithm in (2) and (3) works also when the gradient computations $\nabla f_i(x)$ in update (3) are erroneous with random errors. This corresponds to using a stochastic gradient $\tilde{\nabla} f_i(x)$ instead of $\nabla f_i(x)$, resulting in the following stochastic gradient-projection step:

$$x_i(k+1) = \prod_X \left[v_i(k) - \alpha(k) \tilde{\nabla} f_i(v_i(k)) \right]$$

instead of (3). The convergence of these methods is established for the cases when the stochastic gradients are consistent estimates of the actual gradient, i.e.,

$$\mathbb{E} \left[\tilde{\nabla} f_i(v_i(k)) | v_i(k) \right] = \nabla f_i(v_i(k)).$$

The convergence of these methods typically requires the use of non-summable but square-summable stepsize sequence $\{\alpha(k)\}$ (i.e., $\sum_k \alpha(k) = \infty$ and $\sum_k \alpha^2(k) < \infty$), e.g., Ram et al. (2010a).

- (c) *Noisy or unreliable communication links:* Communication medium is not always perfect and, often, the communication links are characterized by some random noise process. In this case, while agent $j \in N_i$ sends its estimate $x_j(k)$ to agent i , the agent does not receive the intended message. Rather, it receives $x_j(k)$ with some random link-dependent noise $\xi_{ij}(k)$, i.e., it receives $x_j(k) + \xi_{ij}(k)$ instead of $x_j(k)$ (see Kar and Moura 2011; Patterson et al. 2009; Touri and Nedić 2009 for the influence of noise and link failure on consensus). In such cases, the distributed optimization algorithm needs to be modified to include a stepsize for noise attenuation and the standard stepsize for the gradient scaling. These stepsizes are coupled through an appropriate relative-growth conditions which ensure that the gradient information is maintained at the right level and, at the same time, link-noise is attenuated appropriately (Srivastava et al. 2010; Srivastava and Nedić 2011). Other imperfections of the communication links can also be modeled and incorporated into the optimization method, such as link failures and quantization effects, which can be built using the existing results for consensus protocol (e.g., Kar and Moura 2010, 2011; Nedić et al. 2008; Carli et al. 2007).

- (d) *Asynchronous implementations:* The method in (2) and (3) has simultaneous updates, evident in all agents exchanging and updating information in synchronous time steps indexed by k . In some communication

settings, the synchronization of agents is impractical, and the agents are using their own clocks which are not synchronized but do tick according to a common time interval. Such communications result in random weights $w_{ij}(k)$ and random neighbor set $N_i(k) \subseteq E$ in (2), which are typically independent and identically distributed (over time). Most common models are random gossip and random broadcast. In the gossip model, at any time, two randomly selected agents i and j communicate and update, while the other agents sleep (Boyd et al. 2005; Srivastava and Nedić 2011; Kashyap et al. 2007; Ram et al. 2010b; Srivastava 2011). In the broadcast model, a random agent i wakes up and broadcasts its estimate $x_i(k)$. Its neighbors that receive the estimate update their iterates, while the other agents (including the agent who broadcasted) do not update (Aysal et al. 2008; Nedić 2011).

- (e) *Distributed constraints:* One of the more challenging aspects is the extension of the algorithm to the case when the constraint set X in (1) is given as an intersection of closed convex sets X_i , one set per agent. Specifically, the set X in (1) is defined by

$$X = \bigcap_{i=1}^n X_i,$$

where the set X_i is known to agent i only. In this case, the algorithm has a slight modification at the update of $x_i(k+1)$ in (3), where the projection is on the local set X_i instead of X , i.e., the update in (3) is replaced with the following update:

$$x_i(k+1) = \prod_{X_i} \left[v_i(k) - \alpha(k) \nabla f_i(v_i(k)) \right]. \quad (5)$$

The resulting method (2), (5) converges under some additional assumptions on the sets X_i , such as the nonempty interior assumption (i.e., the set $\bigcap_{i=1}^n X_i$ has a nonempty interior), a linear-intersection assumption (each X_i is an intersection of finitely many linear equality and/or inequality constraints), or the

Slater condition (Nedić et al. 2010; Srivastava and Nedić 2011; Srivastava 2011; Lee and Nedić 2012; Zhu and Martínez 2012).

In principle, most of the simple first-order methods that solve a centralized problem of the form (1) can also be distributed among the agents (through the use of consensus protocols) to solve distributed problem (1). For example, the Nesterov dual-averaging subgradient method (Nesterov 2005) can be distributed as proposed in Duchi et al. (2012), a distributed Newton-Raphson method has been proposed and studied in Zanella et al. (2011), while a distributed simplex algorithm has been constructed and analyzed in Bürger et al. (2012). An interesting method based on finding a zero of the gradient $\nabla f = \sum_{i=1}^n \nabla f_i$, distributedly, has been proposed and analyzed in Lu and Tang (2012). Some other distributed algorithms and their implementations can be found in Johansson et al. (2007), Tsianos et al. (2012a, b), Dominguez-Garcia and Hadjicostis (2011), Tsianos (2013), Gharesifard and Cortés (2012a), Jakovetic et al. (2011a, b), and Zargham et al. (2012).

Summary and Future Directions

The distributed optimization algorithms have been developed mainly using consensus protocols that are based on weighted averaging, also known as linear-iterative methods. The convergence behavior and convergence rate analysis of these methods combines the tools from optimization theory, graph theory, and matrix analysis. The main drawback of these algorithms is that they require (at least theoretically) the use of doubly stochastic weight matrix W (or $W(k)$ in time-varying case) in order to solve problem (1). This requirement can be accommodated by allowing agents to exchange locally some additional information on the weights that they intend to use or their degree knowledge. However, in general, constructing such doubly stochastic weights distributedly on directed graphs is rather a complex problem (Gharesifard and Cortés 2012b).

As an alternative, which seems a promising direction for future research, is the use of so-called push-sum protocol (or sum-ratio algorithm) for consensus problem (Kempe et al. 2003; Benezit et al. 2010). This direction is pioneered in Tsianos et al. (2012b), Tsianos (2013), and Tsianos and Rabbat (2011) for static graphs and recently extended to directed graphs Nedić and Olshevsky (2013) for an unconstrained version of problem (1).

Another promising direction lies in the use of alternating direction method of multipliers (ADMM) in combination with the graph-Laplacian formulation of consensus constraints $N_i x_i = \sum_{j \in N_i} x_j$. A nice exposure to ADMM method is given in Boyd et al. (2010). The first work to address the development of distributed ADMM over a network is Wei and Ozdaglar (2012), where a static network is considered. Its distributed implementation over time-varying graphs will be an important and challenging task.

Distributed Sensing for Monitoring Water Distribution Systems

Lina Sela¹ and Waseem Abbas²

¹Department of Civil, Architectural and Environmental Engineering, The University of Texas at Austin, Austin, TX, USA

²Vanderbilt University, Nashville, TN, USA

Abstract

The primary goal of sensing technologies for water systems is to monitor the quantity and quality of water and to collect information pertaining to the physical state of system

components. Combined with advanced modeling and computational tools, data collected from various sensing devices distributed throughout the water network allows for a real-time decision support system for analyzing, modeling, and controlling water supply systems. Since only a limited number of sensors and monitoring devices can be deployed due to physical constraints and limited budget, a crucial design aspect is to determine the best possible locations for these devices within a network. Optimal sensor placement problems in turn depend on several factors including performance objectives under consideration, type of data and measurements being collected from sensors, sensing and detection models used, water distribution system dynamics, and other deployment challenges. In this entry, we provide an overview of these important aspects of sensors deployment in water distribution networks and discuss applications and usefulness of continuously monitoring parameters associated with water system hydraulics and water quality. We also highlight major challenges and future directions of research in this area.

Introduction

Water distribution systems (WDSs) are complex infrastructure systems that span large geographical distances and are responsible for providing water from few points of source (PoS) to numerous points of use (PoU) through thousands to tens of thousands of hydraulic components of the WDS. Intelligent water systems aided by sensing technologies have been identified as a primary mechanism enabling resilient urban systems (Sela Perelman et al. 2016; Sela and Amin 2018). Continuous monitoring of the state of the WDS, PoS, and PoU can support network

operation in terms of real-time flow distribution, pressure management, water quality, and water loss control. Traditionally, the most common hydraulic sensors in water infrastructure systems measure the water level in storage tanks and flow and pressure in pipelines, whereas chlorine, total organic carbon, and pH levels are the focus of the most common water quality sensors (US EPA 2018). Management of modern infrastructures needs advanced sensing technologies, automated data transfer, processing, and computing to provide useful information to water managers to support decision-making. Among many technological components of a modern WDS, this entry focuses on technologies for sensing the performance of hydraulic components and water quality.

Traditionally, the Supervisory Control and Data Acquisition (SCADA) system provides hydraulic and water quality (H&WQ) measurements at remote PoS such as pumping stations, storage tanks, and water treatment facilities. SCADA system keeps operators informed of the states of the water system's key components. Using this information, operators can then react to the conditions and perform control actions, such as emergency shutdowns of processes, starting or stopping pumps, and opening or closing valves. However, due to a limited spatial coverage of the traditional SCADA systems, whose measurements include information only at the few PoS, the collected information prevents monitoring network-wide state of the WDS. It follows that unlike the PoS, the WDSs are highly unmonitored given the small amount of sensing compared to its large scale and huge number of components. On the consumer side, that is, at the PoU, advanced metering infrastructure (AMI) automatically collects and transmits water consumption information at fine temporal-spatial scales. This information has a potential to improve demand management including characterizing end-users and end-uses, modeling demand, identifying opportunities for technology implementation, and guiding infrastructure management and investment decisions. Today, however, AMIs in water infrastructure are primarily used for improved

billing and for limited sharing of information with end-users.

Rapid developments in wireless/wired sensor networks (WSN) for various applications in the built environment have motivated the application of WSN for monitoring WDS, employing different sensors capable of continuously collecting and transmitting H&WQ measurements. In urban WDS, motivating examples of intelligent systems include the PipeNet@Boston (Stoianov et al. 2007), WaterWise@Singapore (Allen et al. 2011), SWND@Bristol (Wright et al. 2015), and WATSUP@Austin (Xing and Sela 2019). Such deployments extend the capabilities of traditional SCADA systems by providing real-time information at a fine spatial-temporal resolution that was previously unavailable and improve water management by monitoring pressure and water quality (Aisopou et al. 2012; Sela and Amin 2018). The application of WSN in water supply systems for securing H&WQ principally focuses on (1) selecting measurable H&WQ parameters that are good indicators of system state and the corresponding sensing technology, (2) deciding on the number and locations of sensors in a WDS, and (3) performing continuous analysis of the data combined with other available information and models for state estimation, event detection, and forecasting. We discuss these important aspects in this entry with a focus on the sensor placement problem in WDS.

In the next section, we discuss some of the common challenges in managing modern WDS that can greatly benefit from advances in sensing technology. We then briefly review common event detection and sensor placement models for monitoring WDS and also provide an overview of challenges faced in sensors deployment. Finally, we present some future directions in this area.

Managing WDS with Sensors

We begin by highlighting some examples of the usefulness of information collected from online H&WQ sensors in routine and emergency operation of water systems. Although traditionally, problems of managing the hydraulic and water

quality integrity of WDSs are treated separately, water quality practices heavily rely on hydraulic applications.

Model calibration is a process of adjusting model parameters to make model prediction consistent with measured data (Ostfeld et al. 2009). The most common WDS parameters for calibration are roughness of pipes, consumer demands, and pump characteristics. While more information can reduce the uncertainty about demands and pump characteristics, the roughness of pipes is not directly observable. By assuming that some partial information pertaining to flows, pressures, and demands in the WDS is available, various calibration approaches have been proposed including (1) trial-and-error, (2) explicit inverse methods for fully determined systems, and (3) implicit inverse optimization methods for overdetermined systems. Due to the limited data availability, calibration of water quality in WDS has been primarily restricted to simulated case studies (Pasha and Lansey 2009). Many WDS problems rely on calibrated models for their management, and advanced sensing and monitoring can greatly contribute to model calibration.

State estimation typically refers to near-real-time estimation of state variables, for instance, flows, pressures, and concentrations, given some limited observations. In WDS, the state estimation problem typically tries to overcome the limitations of conventional forward hydraulic solvers that allow solving fully determined problems for the set of unknown flows and pressures in the system given known end-user demands, pump and valve settings, and water level in tanks. With increasing availability of sensing technologies in WDS and PoU, system observability can be improved, thus alleviating some modeling assumptions and the need for pseudo-measurements (Preis et al. 2011; Vrachimis et al. 2018).

Real-time control involves optimizing pumping schedules to minimize associated energy costs, valve control for pressure management, and operation of booster disinfectant stations for water quality purposes while satisfying changing demands and operational constraints. Ultimately, real-time control depends on the ability to

perform network H&WQ simulations efficiently, the ability of the optimization problem to find good solutions in near-real-time, the effectiveness of state estimation, and making good forecasts of future water demands (Preis et al. 2011). The latter heavily relies on network observability and the available information from distributed sensors.

Event detection has notably received the most attention by the water systems research community in terms of utilizing the information collected by distributed H&WQ sensors. For water quality, events include intentional and unintentional contaminant intrusion into the WDS. For hydraulics, events include the detection and localization of water leaks and pipe bursts (Abbas et al. 2015; Sela Perelman et al. 2016). Sensors are part of a warning system, which integrates data from different sources, performs analysis of the given information, and raises alarms when an event is detected. Subsequent localization of the event can then inform response and recovery actions. The sensor placement problems for detecting contamination events as well as leaks and bursts in WDSs have been well-studied in the literature (Hart and Murray 2010; Sela Perelman et al. 2016).

Condition assessment and hydraulic integrity of pipelines can be indirectly inferred from pressure readings and used to assess the condition and develop risk indicators (Stephens et al. 2012; Zhang et al. 2018). WDS unsteady response to rapid changes is manifested as transient pressure waves traveling through the system. By monitoring pressure and analyzing the pressure signal, the physical condition of the system can be estimated through inverse transient analysis. Raw pressure readings can be converted using various time-frequency domain techniques into distress indicators of pipe aging and deterioration process, blockages, and presence of leaks, thus providing additional benefits to managing WDSs (Xu and Karney 2017).

Event Detection and Sensor Placement Models

A variety of sensors deployed in WDSs that collect data and information regarding the overall

state of the system can be further used to make inferences about potential H&WQ events as follows:

Water quality – contamination event detection methods rely on identifying abnormal behavior of the measured parameters. Online instrumentation capable of continuously measuring and detecting all possible contaminants is impractical to deploy, but the presence of some contaminants can be inferred through measuring surrogate water quality parameters suitable for online monitoring. The main assumption behind monitoring surrogate parameters is that a contaminant transported with the flow will react with some of the routinely monitored water quality parameters; then, detecting irregularities in monitored water quality parameters can give early indication of a potential contamination event in the WDS. The United States Environmental Protection Agency (EPA), academic institutions, and private companies have been conducting research exploring the range of the water quality parameters that are responsive to a variety of contaminants (e.g., pesticides, insecticides, metals, bacteria) and have provided results from experiments that tested the response of commercial water quality sensors of different designs and technologies to chemical and biological loads (US EPA 2015). These tests suggested that free chlorine, total organic carbon (TOC), oxidation reduction potential (ORP), conductivity, and chloride were the most reactive parameters to the majority of contaminants. Hence, information from online water quality sensors deployed in WDS, which are reactive to many contaminants, can provide an early indication of possible pollution, as opposed to intermittent grab sampling targeting specific contaminants (Perelman et al. 2012).

Hydraulics – WDS hydraulics is governed by the flow continuity and energy conservation principles. Thus, disturbances in flows (e.g., leaks and excessive demands) and structure (e.g., valve closure and pipe isolation) cause changes in flows and pressures in the system. The basic premise of model- and data-based detection models is that flow and pressure sensors that continuously collect and transmit information can be utilized for detecting the abovementioned events (Perez et al. 2014; Puust et al. 2010). Since the effect

of medium and small events is relatively local, many flow and pressure sensors need to be deployed in the WDS to achieve good coverage and localization of the events. More precise and accurate surface and inline direct inspection techniques include acoustic, umbilical, and autonomous robots; however, these tools are mostly suitable for local inspections, and their operation is typically time-consuming and expensive, making them not suitable for continuous operation (Zan et al. 2014).

Once the sensing model is established, the detection model, for both water quality and hydraulics, relies on model-based and/or data-driven detection schemes. Data-driven detection ranges from threshold-based models in time-frequency domain (Srirangarajan et al. 2013; Zan et al. 2014) to k -nearest neighbor, logit models, and genetic algorithms (Housh and Ostfeld 2015). Aside from the specific approach, data-driven models process either single- or multi-parameter signals collected from single- or multiple-sensor locations. Model-based

approaches range from simple (Deshpande et al. 2013) to complex hydraulic and water quality models including single- and multi-species using EPANET and EPANET-MSX (Shang et al. 2008).

As discussed next, in practice, several challenges limit the number of sensors that can be deployed within a system. Consequently, it becomes crucial to place sensors at strategic locations such that they provide the most useful information regarding water quality and hydraulics of the WDS. Before formulating and solving the optimal sensor placement problem, the scope of the problem and its components need to be defined, including determining the WDS dynamics, event and sensing characteristics, as well as the impact and performance models. The common design objectives that can be found in the literature include maximizing detection likelihood, minimizing the time to detection, minimizing the volume of delivered contaminated water, and maximizing event localization. The main steps involved in framing the sensor placement problem are summarized in Table 1.

Distributed Sensing for Monitoring Water Distribution Systems, Table 1 Main steps involved in the sensor placement framework

<i>Design steps</i>	<i>Hydraulic features</i>	<i>Water quality features</i>
Process dynamics	Steady-state hydraulics Unsteady hydraulics	Transport and reaction model Single/multi-species
Event characteristics	Excess loads, reduced connectivity Duration, intensity, location Random, strategic	Contaminant intrusion Duration, magnitude, location Random, strategic
Sensor characteristic	Continuous, intermittent Measurements uncertainty, sensor robustness	Continuous, intermittent Measurements uncertainty, sensor robustness
Detection model	Deterministic, stochastic Distance, threshold, model-based	Deterministic, stochastic Distance, threshold, model-based
Impact measure	Detection likelihood, water loss, energy loss	Detection likelihood, contaminated volume, population at risk
Performance measure	Mean, worst case, value at risk	Mean, worst case, value at risk
Solution approach	Engineering principles Network connectivity Model-driven optimization	Engineering principles Network connectivity Model-driven optimization
Testing and validation	Test-bed Simulation	Test-bed Simulations
Routine management activities	Pressure management Leak detection State estimation	Water quality management Residual disinfectant State estimation
Emergency management activities	Network recovery to emergency event Firefighting conditions	Contaminant intrusion Changes in source water quality

To obtain a sensor placement that optimizes one or multiple performance objectives, a number of solution approaches have been proposed in the literature (Rathi and Gupta 2014). *Mixed integer programming (MIP)*, in which the problem is often formulated similar to facility location, was used to accommodate a wide range of design objectives in the formulation and taking advantage of efficient solution schemes for solving large-scale problems (Berry et al. 2006; Sela and Amin 2018). *Greedy approximation* is another useful solution approach, in which sensor locations are typically selected in an iterative manner. In each iteration, a sensor location that optimizes a single or multiple performance objectives under consideration is selected. In many cases, it is also possible to provide performance guarantees of greedy approximations, for instance, if the objective function is submodular (Krause et al. 2008). *Evolutionary algorithms* have also been successfully employed to obtain sensor placements in water networks (Aral et al. 2009). These solution approaches primarily rely on heuristic search techniques and the integration of hydraulic simulations to optimize various performance objectives. *Graph-theoretic* methods have also been proposed, in which the underlying network topology is explored and various network-based centrality measures are suggested to find the optimal sensor locations (Perelman and Ostfeld 2013).

Challenges in Sensors Deployment

Despite the extensive literature, the application of continuous monitoring within water WDS has been limited in practice for several reasons, some of which include:

Cost – high initial investment, operations, and management costs limit the widespread deployment of sensors by budget-constrained water utilities.

Accuracy and reliability – although better and cheaper water quality sensors suitable for continuous deployment in the field are continuously being developed and improved, the low level of reliability of the generated data, frequent calibration requirements, and demanding power needs

introduce additional challenges in field implementation (Aisopou et al. 2012).

Physical constraints – since most of the hydraulic components are buried underground, physical access to locations of interest, while minimizing interference and disruptions to routine operations, additionally hinders the deployment of sensing apparatus within the WDS.

Data management – integration of distributed sensing increases the amount and variety of data generated. For example, sampling water consumption at the PoU at one minute resolution implies replacing the typical 12 annual meter readings with 525,600 readings (Shafiee et al. 2018). Unavoidably, several related challenges in collecting and managing the data are introduced including data heterogeneity necessitates advanced warehousing, cloud dependency requires constant accessibility to the data, and errors can arise from various sources including hardware, firmware, and communication.

Security and privacy – sabotaging and disrupting WDS, physically or through cyber means, could result in catastrophic consequences on population health and dependent infrastructure. Moreover, the access to vast amounts of data generated from various sensing devices across the system must be controlled and regulated to prevent any misuse and to safeguard users' privacy.

Advanced sensing and metering promises benefits to water utilities by enabling intelligent operation and planning decisions. Nevertheless, it is crucial to understand the trade-offs between the information gained from distributed sensors and the associated challenges in deployment and operation. In summary, currently the benefits of smart sensing technologies for WDS have not been realized to their full potential, and there is a need for proven methods for incorporating these cyber-systems in current decision-making processes.

Summary and Future Directions

Information and data collected through an assortment of sensing devices enable water system

operators to continuously monitor, control, and effectively deal with any disruptive events in real time. Despite the many opportunities that advanced sensing and metering technologies create, in the context of WDS, the sensor deployment for contamination events has indisputably received the most attention, while there are still several future research directions in the area of sensor placement in WDS, as we briefly outline next.

Resilience to cyber-physical attacks – in smart water networks, sensing devices are a part of closed, real-time control loops, and hence observed data from them can directly impact the operation of physical infrastructure assets (pumps, valves, tanks). By exploiting vulnerabilities, a malicious attacker can compromise a subset of these devices and attain a certain level of control to manipulate physical processes. Thus, a resilient sensor network that maintains the task of transmitting correct sensor data with minimal and tolerable disruption despite adversarial attack is crucial for a safe water infrastructure. There has been increased focus in recent years toward security and resilience of water distribution systems to malicious disruption (Perelman and Amin 2014; Taormina et al. 2017; Adepu et al. 2019). There is a need to develop analytical tools to assess vulnerabilities and risks associated with malicious attacks on WDS.

Heterogeneous sensors – in WDSs, heterogeneity of sensors can be interpreted and exploited in many different ways for a better performance. Sensors can be heterogeneous in terms of parameters they measure and information they collect about the system's state, such as water flow, pressure, and quality. Another aspect of heterogeneity is that sensors measuring the same network parameter can be of different types and have multiple variants. For instance, they might have distinct operating systems, software packages, and hardware platforms. Diverse implementations of sensing devices can be conducive toward improving the overall security of the sensor network against cyberattacks (Laszka et al. 2019). Sensors can also be heterogeneous in terms of the level of information they provide (Abbas et al. 2015). For instance,

sensors deployed to detect the disturbance in the form of a pressure wave caused by a pipe burst can be single-level in which case they only report the existence of some disturbance without much detail, or they can be multi-level in which case they also report the physical features of the disturbance, such as the intensity, duration, and frequency of the detected disturbance. This information can be helpful in distinguishing between different events. Sensors with better accuracy and more information are typically expensive. Thus, to better exploit cost versus performance trade-off, employing a combination of more expensive and low-priced sensors could yield better results as compared to using only one type of sensors. Interesting problems would then be to determine the right distribution and locations of expensive but highly accurate and low-priced but relatively less accurate sensors within the network. Incorporating these factors in the design of sensor networks for WDS can lead to more effective and applicable solutions in practice.

Modeling framework and benchmarking – optimal sensor locations with respect to any performance criteria highly depend on the selection of network flow, event (disturbance), and sensing models considered during the problem formulation. Several variants of these models have been developed over the years and are used by researchers and practitioners (Hart and Murray 2010). However, there has been little effort in establishing standardized conditions for such formulations, for instance, what hydraulic dynamics should be used? What is the right level of abstraction regarding the network structure? Which event propagation dynamics should be considered? To have sensor placement solutions that work well in practice, it is crucial to clearly understand, outline, and compare the scope of various modeling frameworks. Moreover, although a myriad of optimization tools have been developed for optimal sensor placement, little effort has been made to make these advances accessible to the practitioners, and these tools typically remain limited to the domain of their developers. Some noteworthy freely available software for water quality event detection are

CANARY and PECOS (US EPA 2012; Klise and Stein 2016) and TEVA-SPOT (Berry et al. 2012) for sensor placement.

Disturbance Observers

Hyungbo Shim

Department of Electrical and Computer Engineering, Seoul National University, Seoul, Republic of Korea

Abstract

Disturbance observer is an inner-loop output-feedback controller whose role is to reject external disturbances and to make the outer-loop baseline controller robust against plant's uncertainties. Therefore, the closed-loop system with the DOB approximates the nominal closed-loop by the baseline controller and the nominal plant model with no disturbances. This article presents how the disturbance observer works under what conditions and how one can design a disturbance observer to guarantee robust stability and to recover the nominal performance not only in the steady state but also for the transient response under large uncertainty and disturbance.

Keywords

Robust stabilization · Robust transient response · Disturbance attenuation · Singular perturbation · Normal form

Introduction

The term *disturbance observer* has been used for a few different algorithms and methods in the literature. In this article, we restrict the disturbance observer to imply the inner-loop controller as described conceptually in Fig. 1. This is one that has been employed in many practical applications and verified in industry and is often simply called “DOB.”

The primary goal of DOB is to estimate the external disturbance at the input stage of the plant, which is then used to counteract the exter-

Disturbance Observers,**Fig. 1** Disturbance observer as an inner-loop feedback controller**Disturbance Observers,****Fig. 2** Disturbance observer for a linear plant

nal disturbance as in Fig. 1. This initial idea is extended to deal with the plant's uncertainties when uncertain terms can be lumped into the external disturbance. Therefore, DOB is considered as a method for robust control. More specifically, DOB robustifies the (possibly non-robust) baseline controller. The baseline controller is supposed to be designed for a nominal model of the plant that does not have external disturbances nor uncertainties. By inserting the DOB in the inner-feedback loop, the nominal stability and performance that would have been obtained by the baseline controller and the nominal plant, can be approximately recovered even in the presence of disturbances and uncertainties. There is effectively no restriction on the baseline controller as long as it stabilizes the nominal plant.

When there is no uncertainty and no disturbance with a DOB being equipped, the closed-loop system recovers the nominal performance completely, and as the amount of uncertainty and disturbance grows, the performance degrades gradually while it is still close to the nominal performance. This is in contrast to other robust controls based on the worst-case design, which sacrifices the nominal performance for the worst uncertainty.

Disturbance Observer for Linear System

Let $P(s)$ be the transfer function of a unknown linear plant, $P_n(s)$ be its nominal model, and $C(s)$ be a baseline controller designed for the nominal model $P_n(s)$. Then, the closed-loop system with the DOB can be depicted as Fig. 2. In the figure, $Q(s)$ is a stable low-pass filter whose dc gain is one. The relative degree (i.e., the order of denominator minus the order of numerator) of $Q(s)$ is greater than or equal to the relative degree of $P_n(s)$, so that the block $P_n^{-1}(s)Q(s)$ is proper and implementable. The signals d and r are the external disturbance and the reference, respectively, which are assumed to have little high-frequency components, and the signal n is the measurement noise.

From Fig. 2, the output y in the frequency domain is written as

$$y(s) = \frac{P_n P C}{P_n(1 + PC) + Q(P - P_n)} r(s) + \frac{P_n P(1 - Q)}{P_n(1 + PC) + Q(P - P_n)} d(s) - \frac{P(Q + P_n C)}{P_n(1 + PC) + Q(P - P_n)} n(s). \quad (1)$$

Assume that all the transfer functions are stable (i.e., all the poles have negative real parts), and let ω_c be the cutoff frequency of the low-pass filter so that $Q(j\omega) \approx 1$ for $\omega \ll \omega_c$ and $Q(j\omega) \approx 0$ for $\omega \gg \omega_c$. Therefore, it is seen from (1) that, for $\omega \ll \omega_c$,

$$y(j\omega) \approx \frac{P_n C}{1 + P_n C} r(j\omega) - n(j\omega) \quad (2)$$

and for $\omega \gg \omega_c$ where $d(j\omega) \approx 0$ and $r(j\omega) \approx 0$,

$$\begin{aligned} y(j\omega) &\approx \frac{PC}{1 + PC} r(j\omega) \\ &\quad + \frac{P}{1 + PC} d(j\omega) \\ &\quad - \frac{PC}{1 + PC} n(j\omega) \\ &\approx -\frac{PC}{1 + PC} n(j\omega). \end{aligned}$$

The property (2) is of particular interest because the input-output relation recovers the nominal closed-loop system without being affected by the disturbance d .

The low-pass filter $Q(s)$ is often called “Q-filter” and it is typically given by

$$Q(s) = \frac{a_0}{(\tau s)^\nu + a_{\nu-1}(\tau s)^{\nu-1} + \dots + a_1(\tau s) + a_0}$$

where ν is the relative degree of $P_n(s)$, the coefficients a_i are chosen such that $s^\nu + a_{\nu-1}s^{\nu-1} + \dots + a_0$ be a Hurwitz polynomial, and the constant $\tau > 0$ determines the cutoff frequency.

Robust Stability Condition

The beneficial property (2) is obtained under the assumption that the transfer functions in (1) are stable for all possible uncertain plants $P(s)$. Therefore, it is necessary to design $Q(s)$ (or, choose τ and a_i 's) such that the closed-loop system remains stable for all possible $P(s)$.

In order to deal with uncertain plants having parametric uncertainty, consider the set $\mathcal{P}$ of uncertain transfer functions

$$\mathcal{P} = \left\{ P(s) = g \frac{s^{n-\nu} + \beta_{n-\nu-1}s^{n-\nu-1} + \dots + \beta_0}{s^n + \alpha_{n-1}s^{n-1} + \dots + \alpha_0} : \alpha_i \in [\underline{\alpha}_i, \bar{\alpha}_i], \beta_i \in [\underline{\beta}_i, \bar{\beta}_i], g \in [\underline{g}, \bar{g}] \right\}$$

where the intervals $[\underline{\alpha}_i, \bar{\alpha}_i]$, $[\underline{\beta}_i, \bar{\beta}_i]$, and $[\underline{g}, \bar{g}]$ are known, and $\underline{g} > 0$.

Theorem 1 (Shim and Jo 2009) Assume that (a) the nominal model P_n belongs to $\mathcal{P}$ and the baseline controller C internally stabilizes P_n , (b) all transfer functions in $\mathcal{P}$ are minimum phase, and (c) the coefficients a_i of Q are chosen such that

$$p_f(s) := s^\nu + a_{\nu-1}s^{\nu-1} + \dots + a_1s + \frac{g}{g^*}a_0$$

is Hurwitz for all $g \in [\underline{g}, \bar{g}]$, where $g^* \in [\underline{g}, \bar{g}]$ is the nominal value of g , then there exists $\tau^* > 0$ such that, for all $\tau \leq \tau^*$, the transfer functions in (1) are stable for all $P(s) \in \mathcal{P}$.

The value of τ^* can be computed from the knowledge of the bounds of the intervals in $\mathcal{P}$ (Shim and Jo 2009), but it may also be conservatively chosen based on repeated simulations in practice. Smaller τ implies larger bandwidth of Q-filter, which is desired in the sense that the property (2) holds for larger frequency range.

The proof of Theorem 1 proceeds by observing the closed-loop system in Fig. 2 has $2n + m$ poles where m is the order of $C(s)$. Then one can inspect the behavior of those poles by changing the design parameter τ . For this, let us denote the poles by $\lambda_i(\tau)$, $i = 1, \dots, 2n + m$. Then, it can be shown that

$$\lim_{\tau \rightarrow 0} \tau \lambda_i(\tau) = \lambda_i^*, \quad i = 1, \dots, \nu \quad (3)$$

where λ_i^* , $i = 1, \dots, \nu$, are the roots of $p_f(s)$, and

$$\lim_{\tau \rightarrow 0} \lambda_i(\tau) = \lambda_i^*, \quad i = \nu + 1, \dots, 2n + m$$

where λ_i^* , $i = \nu + 1, \dots, n$, are the zeros of $P(s)$, and λ_i^* , $n + 1, \dots, 2n + m$, are the poles of the nominal closed-loop with $P_n(s)$ and $C(s)$. Thus, Theorem 1 follows.

This argument shows that, if there is no λ_i^* on the imaginary axis, then the conditions (a), (b), and (c) are also necessary for robust stability with sufficiently small τ . It is also seen by (3) that, when $p_f(s)$ is Hurwitz, the poles $\lambda_i(\tau)$, $i = 1, \dots, v$, escape to the negative infinity as $\tau \rightarrow 0$. Therefore, with large bandwidth of $Q(s)$, the closed-loop system shows two-time scale behavior. In fact, it turns out that $p_f(s)$ is the characteristic polynomial of the fast dynamics called “boundary layer system” in the singular perturbation analysis with τ being the parameter of singular perturbation.

Design of $Q(s)$ for Robust Stability

In order to satisfy the condition (c) of Theorem 1, one can choose $\{a_i : i = 1, \dots, v-1\}$ such that

$$s^{v-1} + a_{v-1}s^{v-2} + \dots + a_2s + a_1$$

be a Hurwitz polynomial, and then pick $a_0 > 0$ sufficiently small. Then, the polynomial $p_f(s)$ remains Hurwitz for all variation of $g \in [g, \bar{g}]$.

This can be justified by, for example, the circle criterion. With $G(s) := a_0/(s^v + a_{v-1}s^{v-1} + \dots + a_1s)$ and a static gain (g/g^*) that belongs to the sector $[\underline{g}/g^*, \bar{g}/g^*]$, the characteristic polynomial of the closed-loop system $G(s)/(1 + (g/g^*)G(s))$ becomes $s^v + a_{v-1}s^{v-1} + \dots + a_1s + (g/g^*)a_0$. Therefore, if the Nyquist plot of $G(s)$ does not enter nor encircle the closed disk in the complex plane whose diameter is the line segment connecting $-g^*/\underline{g}$ and $-g^*/\bar{g}$, then $p_f(s)$ is Hurwitz for all variation of $g \in [g, \bar{g}]$. Since $G(s)$ has one pole at the origin and the rest poles have negative real parts, its Nyquist plot is bounded to the direction of real axis. Therefore, by choosing a_0 sufficiently small, the Nyquist plot is disjoint from and does not encircle the disk.

Disturbance Observer for Nonlinear System

Intuitive Introduction of the DOB for Nonlinear System

DOB for nonlinear systems inherits all the ingredients and properties of the DOB for linear

systems. The DOB can be constructed for a class of systems that can be represented by the Byrnes-Isidori normal form in certain coordinates as

$$P : \begin{cases} y = x_1, \\ \dot{x}_i = x_{i+1}, & i = 1, \dots, v-1, \\ \dot{x}_v = f(x, z) + g(x, z)(u + d), \\ \dot{z} = h(x, z, d_z) \end{cases}$$

where $u \in \mathbb{R}$ is the input, $y \in \mathbb{R}$ is the measured output, $x = [x_1, \dots, x_v]^T \in \mathbb{R}^v$ and $z \in \mathbb{R}^{n-v}$ are the states of the n -th order system, and unknown external disturbances are denoted by d and d_z . The disturbances and their first time-derivatives are assumed to be bounded. The functions f and g and the vector field h contain uncertainty. The corresponding nominal model of the plant is considered as

$$P_n : \begin{cases} y = x_1, \\ \dot{x}_i = x_{i+1}, & i = 1, \dots, v-1, \\ \dot{x}_v = f_n(x, z) + g_n(x, z)\bar{u} \\ \dot{z} = h_n(x, z, 0) \end{cases}$$

where $\bar{u}$ represents the input to the nominal model, and the nominal f_n , g_n , and h_n are known. Let us assume all functions and vector fields are smooth.

Assumption 1 (a) A baseline feedback controller

$$C : \begin{cases} \dot{\eta} = \Pi(\eta, y) & \in \mathbb{R}^m, \\ \bar{u} = \pi(\eta, y) \end{cases}$$

stabilizes the nominal model P_n .

(b) The zero dynamics $\dot{z} = h(x, z, d_z)$ is input-to-state stable (ISS) from x and d_z to the state z .

The underlying idea of the DOB is that, if one can apply the input u_{desired} to the plant P , which is generated by

$$\begin{aligned} \dot{\bar{z}} &= h_n(x, \bar{z}) \\ u_{\text{desired}} &= -d + \frac{1}{g(x, z)}(-f(x, z) \\ &\quad + f_n(x, \bar{z}) + g_n(x, \bar{z})\bar{u}) \end{aligned} \quad (4)$$

then the plant P with (4) behaves identical to the nominal model P_n plus $\dot{z} = h(x, z, d_z)$. Then, the plant P with (4) interacts with the baseline controller C , and so, it is stabilized, while the plant's zero dynamics $\dot{z} = h(x, z, d_z)$ becomes stand-alone. However, the zero dynamics is ISS, and so, the state z is bounded under the bounded inputs x and d_z .

This idea is, however, not implementable because d , f , and g , as well as the states x and z in (4), are unknown. It turns out that the role of the DOB is to *estimate* the state x and the signal u_{desired} . In the linear case, the structure of the DOB in Fig. 2 actually does this job (Shim et al 2016).

Implementation of the DOB

The idea of estimating x and u_{desired} is realized in the semi-global sense. Suppose that $S_0 \subset \mathbb{R}^{n+m}$ be a compact set for possible initial conditions $(x(0), z(0), \eta(0))$ and U be a compact subset of region of attraction for the nominal closed-loop system P_n and C , which is assumed to contain a compact set S that is strictly larger than S_0 .

Let S_z and U_x be the projections of S and U to the z -axis and the x -axis, respectively, and let M_d and M_{d_z} be an upper bounds for the norms of d and d_z , respectively. Uncertain f , g , and h are supposed to belong to the sets $\mathcal{F}$, $\mathcal{G}$, and $\mathcal{H}$, respectively, which are defined as follows. Let $\mathcal{H}$ be a collection of uncertain h . For each $h \in \mathcal{H}$, there is a compact set $Z_h \subset \mathbb{R}^{n-v}$ to which all possible states $z(t)$ belongs, where $z(t)$ is the solution to the ISS system $\dot{z} = h(u_1, z, u_2)$ with any $z(0) \in S_z$ and any bounded inputs $u_1(t) \in U_x$ and $\|u_2(t)\| \leq M_{d_z}$. It is assumed that $\mathcal{H}$ is such that there is a compact set $Z \supset \cup_{h \in \mathcal{H}} Z_h$. The set $\mathcal{F}$ is a collection of uncertain f such that, for every $f \in \mathcal{F}$, there are uniform bounds M_f and M_{df} such that $|f(x, z)| \leq M_f$ and $\|\partial f(x, z)/\partial(x, z)\| \leq M_{df}$ on $U_x \times Z$. The set $\mathcal{G}$ is a collection of uncertain g such that, for every $g \in \mathcal{G}$, there are uniform bounds $\underline{g}$, $\bar{g}$, and M_{dg} such that $\|\partial g(x, z)/\partial(x, z)\| \leq M_{dg}$ and

$$0 < \underline{g} \leq g(x, z) \leq \bar{g}, \quad \forall (x, z) \in U_x \times Z.$$

The DOB is illustrated in Fig. 3 and is given by

$$D : \begin{cases} \dot{\bar{z}} = h_n(\text{sat}_x(q), \bar{z}) & \in \mathbb{R}^{n-v} \\ \dot{q} = A(\tau)q + \frac{a_0}{\tau}By & \in \mathbb{R}^v \\ \dot{p} = A(\tau)p + \frac{a_0}{\tau}B \left(\phi - \frac{1}{g^*}(\phi - \text{sat}_\phi(\phi)) + \frac{1}{g^*}w \right) & \in \mathbb{R}^v \\ u = \text{sat}_\phi(\phi) + \frac{1}{g^*}w \end{cases}$$

where

$$\phi = p_1 + \frac{1}{g^*} \left[\frac{a_0}{\tau^v}, \frac{a_1}{\tau^{v-1}}, \dots, \frac{a_{v-1}}{\tau} \right] q - \frac{1}{g^*} \frac{a_0}{\tau^v} y \quad (= p_1 - \frac{\dot{q}_v}{g^*})$$

$$w = f_n(\text{sat}_x(q), \bar{z}) + g_n(\text{sat}_x(q), \bar{z})\bar{u}$$

$$A(\tau) = \begin{bmatrix} 0 & 1 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 1 \\ -\frac{a_0}{\tau^v} & -\frac{a_1}{\tau^{v-1}} & \dots & -\frac{a_{v-1}}{\tau} \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}$$

Disturbance Observers, Fig. 3 Disturbance observer for a nonlinear plant P . The state of $Q(s)$ is p

and g^* is any constant between $\underline{g}$ and $\bar{g}$, $\bar{u}$ is the output of the baseline controller C , and two saturations are globally bounded, continuously differentiable functions such that $\text{sat}_x(x) = x$ for all $x \in U_x$ and $\text{sat}_\phi(\phi) = \phi$ for all $\phi \in S_\phi$ where the interval S_ϕ is given by

$$S_\phi = \left\{ \left(\frac{1}{g(z, x)} - \frac{1}{g^*} \right) (f_n(x, \bar{z}) + g_n(x, \bar{z})\pi(\eta, x_1)) - \frac{f(x, z)}{g(x, z)} - d : z \in Z, (\bar{z}, x, \eta) \in U, |d| \leq M_d, f \in \mathcal{F}, g \in \mathcal{G} \right\}.$$

Suppose that $(\bar{z}(0), q(0), p(0)) \in S_{0z} \times S_{qp}$ where S_{0z} is the projection of S_0 to the z -axis and S_{qp} is any compact set in $\mathbb{R}^{2\nu}$.

In practice, choosing the sets such as U , Z , and S_ϕ may not be easy. If so, conservative choice of them works. Based on repeated simulations or numerical computations, one can take sufficiently large compact sets for them. If everything is linear and the saturations become identity maps in Fig. 3, then the above controller D becomes effectively the same as the state-space realization of the linear DOB in Fig. 2.

Robust Stability

Assumption 1 (c) The coefficients a_i in the DOB are chosen such that $s^{\nu-1} + a_{\nu-1}s^{\nu-2} + \dots + a_1$ is Hurwitz and $a_0 > 0$ is sufficiently

small such that the Nyquist plot of $G(s) := a_0/(s^\nu + a_{\nu-1}s^{\nu-1} + \dots + a_1s)$ is disjoint from and does not encircle the closed disk in the complex plane whose diameter is the line segment connecting $-g^*/\underline{g}$ and $-g^*/\bar{g}$.

Under this assumption, the polynomial

$$p_f(s) := s^\nu + a_{\nu-1}s^{\nu-1} + \dots + a_1s + \frac{g(x, z)}{g^*}a_0$$

is Hurwitz for all frozen states $(x, z) \in U_x \times Z$ and for all uncertain functions $g \in \mathcal{G}$, as discussed in the section “[Design of \$Q\(s\)\$ for Robust Stability](#)”.

Theorem 2 Suppose that the conditions (a), (b), and (c) of Assumption 1 hold. Then, there exists $\tau^* > 0$ such that, for each $\tau \leq \tau^*$, the closed-loop system of P , C , and D is stable for all $f \in \mathcal{F}$, $g \in \mathcal{G}$, and $h \in \mathcal{H}$, and the region of attraction for $(x, z, \eta, \bar{z}, q, p)$ includes $S_0 \times S_{0z} \times S_{qp}$.

To prove the theorem, one can convert the closed-loop system into the standard singular perturbation form with τ being the singular perturbation parameter. Then, it can be seen that the quasi-steady-state system on the slow manifold is simply the nominal closed-loop system of P_n and C without external disturbance d plus the actual zero dynamics $\dot{z} = h(x, z, d_z)$. Since the quasi-steady-state system is assumed to be stable by Assumption 1, the overall system is stable with

sufficiently small τ if the boundary layer system is also stable. Then, it turns out that the boundary layer system is linear since all the slow variables such as $x(t)$ and $z(t)$ are treated as frozen parameters, and the characteristic polynomial of the linear boundary layer system is $p_f(s)$. For details, see Back and Shim (2008).

It can be also seen that, on the slow manifold, all the saturation functions in the DOB become inactive. The role of the saturations is to prevent the peaking phenomenon (Sussmann and Kokotovic 1991) from transferring into the plant. Without saturations, the region of attraction may shrink in general as τ gets smaller, as in Kokotovic and Marino (1986), and only local stability is achieved. On the other hand, even if the plant is protected from the peaking components by the saturation functions, some internal components must peak for fast convergence of the DOB states. In this regard, the role of the dead-zone nonlinearity in Fig. 3 is to allow peaking inside the DOB structure.

Robust Transient Response

Additional benefit of the DOB with saturation functions is robustness of transient response. If the baseline controller C is designed for the nominal model P_n to achieve desired transients such as small overshoot or fast settling time for example, then similar transients can be obtained for the actual plant P under external disturbances by adding the nonlinear DOB to the baseline controller. The same benefit is obtained for the linear case as long as the saturations in Fig. 3 are employed.

Theorem 3 (Back and Shim 2008) *Suppose that the conditions (a), (b), and (c) of Assumption 1 hold. For any given $\epsilon > 0$, there exists $\tau^* > 0$ such that, for each $\tau \leq \tau^*$, the solution of the closed-loop system denoted by $(z(t), x(t), \bar{z}(t), \eta(t))$, initiated in $S_{0z} \times S_0$ with $(q(0), p(0)) \in S_{qp}$, is bounded and satisfies*

$$\left\| \begin{bmatrix} x(t) \\ \bar{z}(t) \\ \eta(t) \end{bmatrix} - \begin{bmatrix} x_N(t) \\ \bar{z}_N(t) \\ \eta_N(t) \end{bmatrix} \right\| \leq \epsilon, \quad \forall t \geq 0$$

where the reference $(x_N(t), \bar{z}_N(t), \eta_N(t))$ is the solution of the nominal closed-loop system of P_n and C with $(x_N(0), \bar{z}_N(0), \eta_N(0)) = (x(0), \bar{z}(0), \eta(0))$.

Since $y = x_1$, this theorem ensures robust transient response that $y(t)$ remains close to its nominal counterpart $y_N(t)$ from the initial time $t = 0$. However, nothing can be said regarding the state $z(t)$ except that it is bounded by the ISS property of the zero dynamics.

Theorem 3 is basically an application of Tikhonov's theorem (Hoppensteadt 1966).

Discussions

- The baseline controller C may depend on a reference r , which is the case for tracking control. Theorems 2 and 3 also hold for this case (Back and Shim 2008).
- If uncertainties are small in modeling so that $f \approx f_n$, $g \approx g_n$, and $h \approx h_n$, then the DOB can be used to estimate the input disturbance d . This is clearly seen from (4).
- Regarding a design of DOB for multi-input-multi-output plants, refer to Back and Shim (2009), which requires well-defined vector relative degree of the plant. For the case of extended state observer (ESO), this requirement has been relaxed in Wu et al (2019).
- If the external disturbance is a sum of a modeled disturbance, which is generated by a known model, and an unmodeled disturbance which is slowly varying, then the modeled disturbance can be exactly canceled by embedding the known model into the DOB structure, while the unmodeled disturbance can still be canceled approximately. This is done by utilizing the internal model principle, and the details can be found in Joo et al (2015).
- For linear systems with mismatched disturbances:

$$\begin{aligned} \dot{\mathbf{x}} &= \mathbf{A}\mathbf{x} + \mathbf{b}u + \mathbf{E}d, & \mathbf{x} &\in \mathbb{R}^n, & u &\in \mathbb{R}, \\ y &= \mathbf{c}\mathbf{x}, & \mathbf{d} &\in \mathbb{R}^q, & y &\in \mathbb{R}, \end{aligned}$$

one can transfer the disturbances into the input stage by redefining the state combined with the disturbances, if the disturbance $\mathbf{d}$ is smooth in t . Indeed, there is a coordinate change $[x^T, z^T]^T = \Phi \mathbf{x} + \Theta[\mathbf{d}^T, \dot{\mathbf{d}}^T, \dots, (\mathbf{d}^{(v-2)})^T]^T$ from $\mathbf{x}$ to (x, z) with a nonsingular matrix Φ , and the system becomes

$$\begin{aligned} y &= x_1, & \dot{x}_i &= x_{i+1}, & i &= 1, \dots, v-1, \\ \dot{x}_v &= F_x x + F_z z + g u + g d \\ \dot{z} &= H_x x + H_z z + d_z \end{aligned}$$

where d and d_z are linear combinations of $\mathbf{d}$ and its derivatives (Shim et al 2016).

- Robust control based on the linear DOB is relatively simple to construct, which is one of the reasons why it is frequently used in industry. Stability condition is often ignored in practice, but as seen in Theorem 1, all three conditions are often automatically met. In particular, with small amount of uncertainty, the condition (c) tends to hold with $g \approx g^*$ for any stable Q-filter because of structural robustness of Hurwitz polynomials.
- In the case of linear DOB, there is another robust stability condition based on the small-gain theorem (Choi et al 2003).
- Basic philosophy of DOB is to treat plant's uncertainties and external disturbances together as a lumped disturbance and to estimate and compensate it. This philosophy is shared with other similar approaches such as *extended state observer (ESO)* (Freidovich and Khalil 2008) and *active disturbance rejection control (ADRC)* (Han 2009). The DOB also has been reviewed with comparison to other similar methods in Chen et al (2015).

Summary and Future Directions

Underlying theory for the disturbance observer is presented. The analysis is mainly based on large bandwidth of Q-filter. However, there are cases when the bandwidth cannot be increased in practice because of limited sampling rate in discrete-time implementation. Further study is

necessary to achieve satisfactory performance for discrete-time design of DOB.

Abstract

Wireless communication is known to play a pivotal role in enabling teams of robots to successfully accomplish global coordinated tasks. In fact, network connectivity is an underlying assumption in every distributed control and optimization algorithm. For this reason, in recent years, there is a growing research in designing controllers that ensure point-to-point or end-to-end network connectivity for all time. Such controllers either rely on graph theory to model robot communication or employ more realistic communication models that take into account path loss, shadowing, and multipath fading. Nevertheless, maintaining all-time connectivity can severely restrict the robots from accomplishing their tasks, as motion planning is always constrained by network connectivity constraints. Therefore, intermittent connectivity controllers have recently been proposed, as well, that allow the robots to communicate in an intermittent fashion and operate in disconnect mode

the rest of the time. This entry provides an overview of all-time and intermittent connectivity controllers.

Introduction

Graph-Theoretic Connectivity Control

Recent methods for communication control of mobile robot networks typically rely on proximity graphs to model the exchange of information among the robots, and, therefore, the communication problem becomes equivalent to preserving graph connectivity. Methods to control graph connectivity typically rely on controlling the Fiedler value of the underlying graph. One possible way of doing so is maximizing the Fiedler value in a centralized (Kim and Mesbahi 2006) or distributed (DeGennaro and Jadbabaie 2006) fashion. Alternatively, potential fields that model loss of connectivity as an obstacle in the free space can be employed for this purpose, as shown in Zavlanos and Pappas (2007). A distributed hybrid approach to connectivity control is presented in Zavlanos and Pappas (2008), whereby communication links are efficiently manipulated by decoupling the continuous robot motion from the control of the discrete graph. Further distributed algorithms for graph connectivity maintenance have been implemented in Notarstefano et al. (June 2006), Ji and Egerstedt (2007), and Sabattini et al. (2013). A comprehensive survey of this literature can be found in Mesbahi and Egerstedt (2010) and Zavlanos et al. (2011).

Connectivity Control Using Realistic Communication Models

In practice, the above graph-based communication models turn out to be rather conservative, since proximity does not necessarily imply

tangible and reliable communication. More realistic communication models for mobile networks compared to the above graph-theoretic models are proposed in Zavlanos et al. (2010, 2013) and Stephan et al. (2017) that take into account the routing of packets as well as desired bounds on the transmitted rates. The key idea in these works is to define connectivity in terms of communication rates and to use optimization methods to determine optimal operating points of wireless networks. A conceptually similar communication model is proposed in Fink et al. (2010). Integration of these communication frameworks with area coverage control and navigation tasks in complex environments is presented in Kantaros and Zavlanos (2016b, a); see also Fig. 1a. A communication model that accounts for multipath fading of channels is proposed in Lindhé and Johansson (2010), where robot mobility is exploited in order to increase the throughput. Multipath fading, shadow fading, and path loss have also been used to model channels in Mostofi et al. (2010); Malmirchegini and Mostofi (2012). In these works, a probabilistic framework for channel prediction is developed based on a small number of measurements of the received signal power. The integration of the latter communica-

tion models with robot mobility is described in Ghaffarkhah and Mostofi (2010).

Intermittent Connectivity Control

Common in the above works is that point-to-point or end-to-end network connectivity is required to be preserved for all time. However, due to the uncertainty in the wireless channel, it is often impossible to ensure all-time connectivity in practice. Moreover, all-time connectivity constraints may prevent the robots from moving freely in their environment to fulfill their tasks and instead favor motions that maintain a reliable communication network. Motivated by this fact, intermittent communication frameworks have recently been proposed that allow the robots to communicate intermittently and operate in disconnect mode the rest of the time. Specifically, Hollinger and Singh (2010) and Hollinger et al. (2012) propose a receding horizon framework for periodic connectivity that ensures recovery of connectivity within a given time horizon. A similar recurrent connectivity framework for planning on environments modeled as graphs is proposed in Banfi et al. (2018). Unlike these approaches that require the whole network to become occasionally reconnected, alternative

Dynamic Graphs, Connectivity of, Fig. 1 (a) shows a communication network consisting of 14 robots (black dots) that are tasked with optimally sensing two sources, whose density is captured in yellow, while reliably transmitting the collected information to two access points (blue rhombuses). The thickness of communication links (green edges) depends on their reliability. (b) illustrates a joint task planning and intermittent connectivity frame-

work. The robots have to accomplish complex tasks, such as data gathering, by visiting the green waypoints, and exchange the collected information by communicating intermittently when they simultaneously visit the communication points (red squares). The teams are defined as $\mathcal{T}_1 = \{1, 2\}$, $\mathcal{T}_2 = \{2, 3\}$, and $\mathcal{T}_3 = \{1, 3\}$. The corresponding team membership graph is shown in (c)

approaches have been recently proposed that do not require the whole communication network to ever become connected at once, but they ensure connectivity over time, infinitely often (Zavlanos 2010). The key idea is to divide the robots into $M > 0$ smaller teams $\{\mathcal{T}_m\}_{m=1}^M$, where M is user-specified, and require that communication events take place when the robots in every team meet at a common location in space that can be fixed or optimally selected; see also Fig. 1b. While in disconnect mode, the robots can accomplish other tasks free of communication constraints. The teams $\mathcal{T}_m$ are constructed so that every robot belongs to at least one team giving rise to a team membership graph $\mathcal{G}_{\mathcal{T}} = (\mathcal{V}_{\mathcal{T}}, \mathcal{E}_{\mathcal{T}})$, where the set of nodes $\mathcal{V}_{\mathcal{T}}$ is indexed by the teams $\mathcal{T}_m$ and set of edges $\mathcal{E}_{\mathcal{T}}$ is defined as $\mathcal{E}_{\mathcal{T}} = \{(m, n) | \mathcal{T}_m \cap \mathcal{T}_n \neq \emptyset, \forall m, n \in \mathcal{V}_{\mathcal{T}}, m \neq n\}$. Assuming that the team membership graph $\mathcal{G}_{\mathcal{T}}$ is a connected bipartite graph, Zavlanos (2010) proposes a distributed control scheme that achieves periodic communication events, synchronously, at meeting/communication locations. Arbitrary connected team graphs are considered in Kantaros and Zavlanos (2017) and Kantaros and Zavlanos (2016c) where techniques from formal methods are employed to synthesize correct-by-construction discrete plans (schedules) that determine the order in which communication events should occur at the meeting locations. Specifically, in these works, intermittent connectivity is captured by the following global linear temporal logic (LTL) formula:

$$\phi = \wedge_{m \in \mathcal{M}} \left(\square \diamond \left(\bigvee_{j \in \mathcal{C}_m} (\wedge_{i \in \mathcal{T}_m} \pi_i^{\mathbf{v}_j}) \right) \right), \quad (1)$$

that requires all robots in a team $\mathcal{T}_m$ to meet infinitely often at a common communication point, denoted by $\mathbf{v}_j$, for all teams $\mathcal{T}_m$. In (1), $\pi_i^{\mathbf{v}_j}$ is a Boolean variable that is true if robot i is in location $\mathbf{v}_j$, and $\mathcal{C}_m$ is a set that collects all communication points $\mathbf{v}_j$ available to team $\mathcal{T}_m$. Also, $\square \diamond$ represents the infinitely often requirement. A detailed presentation of LTL semantics can be found in Baier and Katoen (2008). Then, Kantaros and Zavlanos

(2017, 2016c) propose a distributed control synthesis algorithm to synthesize schedules that satisfy ϕ . Integration of this intermittent connectivity framework with temporal logic task planning, state estimation tasks, and planning for time-critical and dynamic tasks is proposed in Kantaros et al. (2019), Khodayi-mehr et al. (2019), and Kantaros and Zavlanos (2018), respectively. An intermittent communication framework for starlike communication topologies is also presented in Guo and Zavlanos (2018) that considers information flow only to the root/user and not among the robots.

Summary and Future Research Directions

Network connectivity is an underlying assumption in every distributed control and optimization algorithm. As a result, all-time connectivity controllers that either rely on graph theory to model robot communication or employ more realistic communication models have been proposed to control communication between nodes. When all-time communication is impossible or very restrictive of a condition, intermittent connectivity controllers can be used that allow the robots to communicate in an intermittent fashion and operate in disconnect mode the rest of the time. Intermittent connectivity control in unknown and dynamic environments, such as crowded human environments or underwater environments, and resilient intermittent connectivity controllers that are, e.g., robust to robot failures are interesting future research directions.

Dynamic Noncooperative Games

David A. Castañón
Boston University, Boston, MA, USA

Abstract

In this entry, we present models of dynamic noncooperative games, solution concepts and

algorithms for finding game solutions. For the sake of exposition, we focus mostly on finite games, where the number of actions available to each player is finite, and discuss briefly extensions to infinite games.

Keywords

Extensive form games · Finite games · Nash equilibrium

Introduction

Dynamic noncooperative games allow multiple actions by individual players, and include explicit representations of the information available to each player for selecting its decision. Such games have a complex temporal order of play and an information structure that reflects uncertainty as to what individual players know when they have to make decisions. This temporal order and information structure is not evident when the game is represented as a static game between players that select strategies. Dynamic games often incorporate explicit uncertainty in outcomes, by representing such outcomes as actions taken by a random player (called chance or “Nature”) with known probability distributions for selecting its actions.

We focus our exposition on models of finite games and discuss briefly extensions to infinite games at the end of the entry.

Finite Games in Extensive Form

The *extensive form* of a game was introduced by von Neumann (1928) and later refined by Kuhn (1953) to represent explicitly the order of play, the information and actions available to each player for making decisions at each of their turns, and the payoffs that players receive after a complete set of actions. Let $I = \{0, 1, \dots, n\}$ denote the set of players in a game, where player 0 corresponds to Nature. The extensive form is represented in terms of a game tree, consisting of a rooted tree with nodes $\mathcal{N}$ and edges $\mathcal{E}$. The

root node represents the initial state of the game. Nodes x in this tree correspond to positions or “states” of the game. Any non-root node with more than one incident edge is an internal node of the tree and is a *decision* node associated with a player in the game; the root node is also a decision node. Each decision node x has a player $o(x) \in I$ assigned to select a decision from a finite set of admissible decisions $A(x)$. Using distance from the root node to indicate direction of play, each edge that follows node x corresponds to an action in $A(x)$ taken by player $p(x)$, which evolves the state of the game into a subsequent node x' .

Non-root nodes with only one incident edge are terminal nodes, which indicate the end of the game; such nodes represent outcomes of the game. The unique path from the root node to a terminal node is called a *play* of the game. For each outcome node x , there are payoff functions $J_i(x)$ associated with each player $i \in \{1, \dots, n\}$.

The above form represents the different players, the order in which players select actions and their possible actions, and the resulting payoffs to each player from a complete set of plays of the game. The last component of interest is to represent the information available for players to select decisions at each decision node. Due to the tree structure of the extensive form of a game, each decision node x contains exact information on all of the previous actions taken that led to state x . In games of *perfect information*, each player knows exactly the decision node x at which he/she is selecting an action. To represent imperfect information, the extensive form uses the notion of an *information set*, which represents a group of decision nodes, associated with the same player, where the information available to that player is that the game is in one of the states in that information set. Formally, let $\mathcal{N}_i \subset \mathcal{N}$ be the set of decision nodes associated with player i , for $i \in I$. Let $\mathcal{H}_i$ denote a partition of $\mathcal{N}_i$ so that, for each set $h_i^k \in \mathcal{H}_i$, we have the following properties:

- If $x, x' \in h_i^k$, then they have the same admissible actions: $A(x) = A(x')$.

- If $x, x' \in h_i^k$, then they cannot both belong to a play of the game; that is, both x and x' cannot be on a path from the root node to an outcome.

Elements h_i^k for some player i are the *information sets*. Each decision node x belongs to one and only one information set associated with player $p(x)$. The constraints above ensure that, for each information set, there is a unique player identified to select actions, and the set of admissible actions is unambiguously defined. Denote by $A(h_i^k)$ the set of admissible actions at information set h_i^k . The last condition is a causality condition that ensures that a player who has selected a previous decision remembers that he/she has already made that previous decision.

Figure 1 illustrates an extensive form for a two-person game. Player 1 has two actions in any play of the game, whereas player 2 has only 1 action. Player 1 starts the game at the root node a ; the information set h_1^1 shows that player 2 is unaware of this action, as both nodes that descend from node a are in this information set. After player 2's action, player 1 gets to select a second action. However, the information sets h_1^2, h_1^3 indicate that player 1 recalls what earlier action

he/she selected, but he/she has not observed the action of player 2. The terminal nodes indicate the payoffs to player 1 and player 2 as an ordered pair.

Strategies and Equilibrium Solutions

A pure strategy γ_i for player $i \in \{1, \dots, n\}$ is a function that maps each information set of player i into an admissible decision. That is,

$$\gamma_i : \mathcal{H}_i \rightarrow A$$

such that $\gamma_i(h_i^k) \in A(h_i^k)$. The set of pure strategies for player i is denoted as Γ_i .

Note that pure strategies do not include actions selected by Nature. Nature's actions are selected using probability distributions over the choices available for the information sets corresponding to Nature, where the choice at each information set is made independently of other choices. For finite games, the number of pure strategies for each player is also finite. Given a tuple of pure strategies $\underline{\gamma} = (\gamma_1, \dots, \gamma_n)$, we can define the probability of the play of the game resulting in outcome node x as $\pi(x)$, computed as follows: Each outcome node has a unique path (the play) p_{rx} from root node r . We initialize $\pi(r) = 1$ and node $n = r$. If the player at node n is Nature and the next node in p_{rx} is n' , then $\pi(n') = \pi(n) * p(n, n')$, where $p(n, n')$ is the probability that Nature chooses the action that leads to n' . Otherwise, let $i = p(n)$ be the player at node n and let $h_i^k(n)$ denote the information set containing node n . Then, if $\gamma^i(h_i^k(n)) = a(n, n')$, let $\pi(n') = \pi(n)$, where $a(n, n')$ is the action in $A(n)$ that leads to n' ; otherwise, set $\pi(n') = 0$. The above process is repeated letting $n' = n$, until n' equals the terminal node x . Using these probabilities, the resulting expected payoff to player i is

Dynamic Noncooperative Games, Fig. 1 Illustration of game in extensive form

$$J_i(\underline{\gamma}) = \sum_{x \text{ terminal}, x \in \mathcal{N}} \pi(x) J_i(x)$$

This representation of payoffs in terms of strategies transforms the game from an extensive form representation to a strategic or normal form representation, where the concept of dynamics and information has been abstracted away. The resulting strategic form looks like a static game as discussed in the encyclopedia entry ► [Strategic Form Games and Nash Equilibrium](#), where each player selects his/her strategy from a finite set, resulting in a vector of payoffs for the players. Using these payoffs, one can now define solution concepts for the game. Let the notation $\underline{\gamma}_{-i} = (\gamma_1, \dots, \gamma_{i-1}, \gamma_{i+1}, \gamma_n)$ denote the set of strategies in a tuple excluding the i th strategy. A Nash equilibrium solution is a tuple of feasible strategies $\underline{\gamma}^* = (\gamma_1^*, \dots, \gamma_n^*)$ such that

$$\begin{aligned} J_i(\underline{\gamma}^*) &\geq J_i(\underline{\gamma}_{-i}^*, \gamma_i) \text{ for all } \gamma_i \in \Gamma_i, \\ \text{for all } i &\in \{1, \dots, n\} \end{aligned} \quad (1)$$

The special case of two-person games where $J_1(\underline{\gamma}) = -J_2(\underline{\gamma})$ are known as zero-sum games.

As discussed in the encyclopedia entry on static games (► [Strategic Form Games and Nash Equilibrium](#)), the existence of Nash equilibria or even saddle point strategies in terms of pure strategies is not guaranteed for finite games. Thus, one must consider the use of *mixed strategies*. A mixed strategy μ_i for player $i \in \{1, \dots, n\}$ is a probability distribution over the set of pure strategies Γ_i . The definition of payoffs can be extended to mixed strategies by averaging the payoffs associated with the pure strategies, as

$$J_i(\underline{\mu}_i) = \sum_{\gamma_1 \in \Gamma_1} \dots \sum_{\gamma_n \in \Gamma_n} \mu_1(\gamma_1) \dots \mu_n(\gamma_n) J_i(\gamma_1, \dots, \gamma_n)$$

Denote the set of probability distributions over Γ_i as $\Delta(\Gamma_i)$. An n -tuple $\underline{\mu}^* = (\mu_1, \dots, \mu_n)$ of mixed strategies is said to be a Nash equilibrium if

$$\begin{aligned} J_i(\underline{\mu}^*) &\geq J_i(\underline{\mu}_{-i}^*, \mu_i) \text{ for all } \mu_i \\ &\in \Delta(\Gamma_i), \text{ for all } i \in \{1, \dots, n\} \end{aligned}$$

Theorem 1 (Nash 1950, 1951) *Every finite n -person game has at least one Nash equilibrium point in mixed strategies.*

Mixed strategies suggest that each player's randomization occurs before the game is played, by choosing a strategy at random from its choices of pure strategies. For games in extensive form, one can introduce a different class of strategies where a player makes a random choice of action at each information set, according to a probability distribution that depends on the specific information set. The choice of action is selected independently at each information set according to a selected probability distribution, in a manner similar to how Nature's actions are selected. These random choice strategies are known as *behavior strategies*. Let $\Delta(A(h_i^k))$ denote the set of probability distributions over the decisions $A(h_i^k)$ for player i at information set h_i^k . A behavior strategy for player i is an element $x_i \in \prod_{h_i^k \in \mathcal{H}_i} \Delta(A(h_i^k))$, where $x_i(h_i^k)$ denotes the probability distribution of the behavior strategy x_i over the available decisions at information set h_i^k .

Note that the space of admissible behavior strategies is much smaller than the space of admissible mixed strategies. To illustrate this, consider a player with K information sets and two possible decisions for each information set. The number of possible pure strategies would be 2^K , and thus the space of mixed strategies would be a probability simplex of dimension $2^K - 1$. In contrast, behavior strategies would require specifying probability distributions over two choices for each of K information sets, so the space of behavior strategies would be a product space of K probability simplices of dimension 1, totaling dimension K . One way of understanding this difference is that mixed strategies introduce correlated randomization across choices at different information sets, whereas behavior strategies introduce independent randomization across such choices.

For every behavior strategy, one can find an equivalent mixed strategy by computing the probabilities of every set of actions that result from the behavior strategy. The converse is not true for general games in extensive form. However,

there is a special class of games for which the converse is true. In this class of games, players recall what actions they have selected previously and what information they knew previously. A formal definition of perfect recall is beyond the scope of this exposition but can be found in Hart (1991) and Kuhn (1953). The implication of perfect recall is summarized below:

Theorem 2 (Kuhn 1953) *Given a finite n -person game in which player i has perfect recall, for each mixed strategy μ_i for player i , there exists a corresponding behavior strategy x_i that is equivalent, where every player receives the same payoffs under both strategies μ_i and x_i .*

This equivalence was extended by Aumann to infinite games (Aumann 1964). In dynamic games, it is common to assume that each player has perfect recall and thus solutions can be found in the smaller space of behavior strategies.

Computation of Equilibria

Algorithms for the computation of mixed-strategy Nash equilibria of static games can be extended to compute mixed-strategy Nash equilibria for games in extensive form when the pure strategies are enumerated as above. However, the number of pure strategies grows exponentially with the size of the extensive form tree, making these methods hard to apply. For two-person games in extensive form with perfect recall by both players, one can search for Nash equilibria in the much smaller space of behavior strategies. This was exploited in Koller et al. (1996) to obtain efficient linear complementarity problems for nonzero-sum games and linear programs for zero-sum games where the number of variables involved is linear in the number of internal decision nodes of the extensive form of the game. A more detailed overview of computation algorithms for Nash equilibria can be found in McKelvey and McLennan (1996). The Gambit Web site (McKelvey et al. 2010) provides software implementations of several techniques for computation of Nash equilibria in two- and n -person games.

An alternative approach to computing Nash equilibria for games in extensive forms is based on subgame decomposition, discussed next.

Subgames

Consider a game G in extensive form. A node c is a successor of a node n if there is a path in the game tree from n to c . Let h be a node in G that is not terminal and is the only node in its information set. Assume that if a node c is a successor of h , then every node in the information set containing c is also a successor of h . In this situation, one can define a subgame H of G with root node h , which consists of node h and its successors, connected by the same actions as in the original game G , with the payoffs and terminal vertices equal to those in G . This is the subgame that would be encountered by the players had the previous play of the game reached the state at node h . Since the information set containing node h contains no other node and all the information sets in the subgame contain only nodes in the subgame, then every player in the subgame knows that they are playing only in the subgame once h has been reached.

Figure 2 illustrates a game where every non-terminal node is contained in its own information set. This game contains a subgame rooted at node c . Note that the full game has two Nash equilibria in pure strategies: strategies (L, L) and (R, R) . However, strategy (L, L) is inconsistent with how player 2 would choose its decision if it were to find itself at node c . This inconsistency arises because the Nash equilibria are defined in terms of strategies announced before the game is played and may not be a reasonable way to select decisions if unanticipated plays occur. When player 1 chooses L , node c should not be reached in the play of the game, and thus player 2 can choose L because it does not affect the expected payoff. One can define the concept of Nash equilibria that are sequentially consistent as follows.

Let x_i be behavior strategies for player i in game G . Denote the restriction of these strategies to the subgame H as x_i^H . This restriction describes the probabilities for choices of actions for the information sets in H . Suppose the game

Dynamic Noncooperative Games, Fig. 2 Simple game with multiple Nash equilibria

G has a Nash equilibrium achieved by strategies $(x_1, \dots, x_n)$. This Nash equilibrium is called *subgame perfect* (Selten 1975) if, for every subgame H of G , the strategies $(x_1^H, \dots, x_n^H)$ are a Nash equilibrium for the subgame H . In the game in Fig. 2, there is only one subgame perfect equilibrium, which is (R, R) . There are several other refinements of the Nash equilibrium concept to enforce sequential consistency, such as sequential equilibria (Kreps and Wilson 1982).

An important application of subgames is to compute subgame perfect equilibria by backward induction. The idea is to start with a subgame root node as close as possible to an outcome node (e.g., node c in Fig. 2). This small subgame can be solved for its Nash equilibria, to compute the equilibrium payoffs for each player. Then, in the original game G , the root node of the subgame can be replaced by an outcome node, with payoffs equal to the equilibrium payoffs in the subgame. This results in a smaller game, and the process can be applied inductively until the full game is solved. The subgame perfect equilibrium strategies can then be computed as the solution of the different subgames solved in this backward induction process. For Fig. 2, the subgame at c is solved by player 2 selecting R , with payoffs $(4,1)$. The reduced new game has two choices for player 1, with best decision R . This leads to the overall subgame perfect equilibrium (R, R) .

This backward induction procedure is similar to the dynamic programming approach to solving control problems. Backward induction was first

used by Zermelo (1912) to analyze zero-sum games of perfect information such as chess. An extension of Zermelo's work by Kuhn (1953) establishes the following result:

Theorem 3 *Every finite game of perfect information has a subgame perfect Nash equilibrium in pure strategies.*

This result follows because, at each step in the backward induction process, the resulting subgame consists of a choice among finite actions for a single player, and thus a pure strategy achieves the maximal payoff possible.

Infinite Noncooperative Games

When the number of options available to players is infinite, game trees are no longer appropriate representations for the evolution of the game. Instead, one uses state space models with explicit models of actions and observations. A typical multistage model for the dynamics of such games is

$$\begin{aligned} x(t+1) &= f(x(t), u_1(t), \dots, u_n(t), w(t), t), \\ t &= 0, \dots, T-1 \end{aligned} \quad (2)$$

with initial condition $\underline{x}(0) = w(0)$, where $x(t)$ is the state of the game at stage t , and $u_1(t), \dots, u_n(t)$ are actions selected by players $1, \dots, n$ at stage t , and $w(t)$ is an action selected by Nature at stage t . The space of actions for each player are restricted at each time to infinite sets $A_i(t)$ with an appropriate topological structure, and the admissible state $x(t)$ at each time belongs to an infinite set X with a topological structure. In terms of Nature's actions, for each stage t , there is a probability distribution that specifies the choice of Nature's action $w(t)$, selected independently of other actions.

Equation (2) describes a play of the game, in terms of how different actions by players at the various stages evolve the state of the game. A play of the game is thus a history $\underline{h} = (x(0), u_1(0), \dots, u_n(0), x(1), u_1(1), \dots, u_n(1), \dots, x(T))$. Associated with each play of the game is a set of real-valued functions $J_i(\underline{h})$

that indicates the payoff to player i in this play. This function is often assumed to be separable across the variables in each stage.

To complete the description of the extensive form, one must now introduce the available information to each player at each stage. Define observation functions

$$y_i(t) = g_i(x(t), v(t), t), \quad i = 1, \dots, n$$

where $y_i(t)$ takes values in observations spaces which may be finite or infinite, and $v(t)$ are selected by Nature given their probability distributions, independent of other selections. Define the information available for player i at stage t to be $I_i(t)$, a subset of $\{y_1(0), \dots, y_n(0), \dots, y_1(t), \dots, y_n(t); u_1(0), \dots, u_n(0), \dots, u_1(t-1), \dots, u_n(t-1)\}$. With this notation, strategies $\gamma_i(t)$ for player i are functions that map, at each stage, the available information $I_i(t)$ into admissible decisions $u_i(t) \in A_i(t)$. With appropriate measurability conditions, specifying a full set of strategies $\underline{\gamma} = (\gamma_1, \dots, \gamma_n)$ for each of the players induces a probability distribution on the plays of the game, which leads to the expected payoff $J_i(\underline{\gamma})$. Nash equilibria are defined in identical fashion to (1).

Obtaining solutions of multistage games is a difficult task that depends on the ability to use the subgame decomposition techniques discussed previously. Such subgame decompositions are possible when games do not include actions by Nature and the payoff functions have a stagewise additive property. Under such cases, backward induction allows the construction of Nash equilibrium strategies through the recursive solutions of static infinite games, such as those discussed in the encyclopedia entry on static games.

Generalizations of multistage games to continuous time result in differential games, covered in two articles in the encyclopedia, but for the zero-sum case. Additional details on infinite dynamic noncooperative games, exploiting different models and information structures and studying the existence, uniqueness, or nonuniqueness of equilibria, can be found in Basar and Olsder (1982).

Conclusions

In this entry, we reviewed models for dynamic noncooperative games that incorporate temporal order of play and uncertainty as to what individual players know when they have to make decisions. Using these models, we defined solution concepts for the games and discussed algorithms for determining solution strategies for the players. Active directions of research include development of new solution concepts for dynamic games, new approaches to computation of game solutions, the study of games with a large number of players, evolutionary games where players' greedy behavior evolves toward equilibrium strategies, and special classes of dynamic games such as Markov games and differential games. Several of these topics are discussed in other entries in the encyclopedia.

Dynamic Positioning Control Systems for Ships and Underwater Vehicles

Asgeir J. Sørensen

Department of Marine Technology, Centre for Autonomous Marine Operations and Systems (AMOS), Norwegian University of Science and Technology, NTNU, Trondheim, Norway

Abstract

In 2012 the fleet of dynamically positioned (DP) ships and rigs was probably larger than 3,000 units, predominately operating in the offshore oil and gas industry. The complexity and functionality vary subject to the targeted marine operation, vessel concept, and risk level. DP systems with advanced control functions and redundant sensor, power, and thruster/propulsion configurations are designed in order to provide high-precision fault-tolerant control in safety-critical marine operations. The DP system is customized for the particular application with integration to other control systems, e.g., power management, propulsion, drilling, oil and gas production, off-loading, crane operation, and pipe and cable laying. For underwater vehicles such as remotely operated vehicles (ROVs) and autonomous underwater vehicles (AUVs),

DP functionality also denoted as *hovering* is implemented on several vehicles.

Keywords

Autonomous underwater vehicles (AUVs) · Fault-tolerant control · Remotely operated vehicles (ROVs)

Introduction

The offshore oil and gas industry is the dominating market for DP vessels. The various offshore applications include offshore service vessels, drilling rigs (semisubmersibles) and ships, shuttle tankers, cable and pipe layers, floating production, storage, and off-loading units (FPSOs), crane and heavy lift vessels, geological survey vessels, rescue vessels, and multipurpose construction vessels. DP systems are also installed on cruise ships, yachts, fishing boats, navy ships, tankers, and others.

A DP vessel is by the International Maritime Organization (IMO) and the maritime class societies (DNV GL, ABS, LR, etc.) defined as *a vessel that maintains its position and heading (fixed location denoted as stationkeeping or pre-determined track) exclusively by means of active thrusters*. The DP system as defined by class societies is not only limited to the DP control system including computers and cabling. Position reference systems of various types measuring North-East coordinates (satellites, hydroacoustic, optics, taut wire, etc.), sensors (heading, roll, pitch, wind speed and direction, etc.), the power system, thruster and propulsion system, and independent joystick system are also essential parts of the DP system. In addition, the DP operator is an important element securing safe and efficient DP operations. Further development of human-machine interfaces, alarm systems, and operator decision support systems is regarded as top priority bridging advanced and complex technology to safe and efficient marine operations. Sufficient DP operator training is a part of this.

The thruster and propulsion system controlled by the DP control system is regarded as one of

the main power consumers on the DP vessel. An important control system for successful integration with the power plant and the other power consumers such as drilling system, process system, heating, and ventilation system is the power and energy management system (PMS/EMS) balancing safety requirements and energy efficiency. The PMS/EMS controls the power generation and distribution and the load control of heavy power consumers. In this context both transient and steady-state behaviors are of relevance. A thorough understanding of the hydrodynamics, dynamics between coupled systems, load characteristics of the various power consumers, control system architecture, control layers, power system, propulsion system, and sensors is important for successful design and operation of DP systems and DP vessels.

Thruster-assisted position mooring is another important stationkeeping application often used for FPSOs, drilling rigs, and shuttle tanker operations where the DP system has to be redesigned accounting for the effect of the mooring system dynamics. In thruster-assisted position mooring, the DP system is renamed to position mooring (PM) system. PM systems have been commercially available since the 1980s. While for DP-operated ships the thrusters are the sole source of the stationkeeping, the assistance of thrusters is only complementary to the mooring system. Here, most of the stationkeeping is provided by a deployed anchor system. In severe environmental conditions, the thrust assistance is used to minimize the vessel excursions and line tension by mainly increasing the damping in terms of velocity feedback control and adding a bias force minimizing the mean tensions of the most loaded mooring lines. Modeling and control of turret-anchored ships are treated in Strand et al. (1998) and Nguyen and Sørensen (2009).

Overview of DP systems including references can be found in Fay (1989), Fossen (2011), and Sørensen (2011). The scientific and industrial contributions since the 1960s are vast, and many research groups worldwide have provided important results. In Sørensen et al. (2012), the development of DP system for ROVs is presented.

Mathematical Modeling of DP Vessels

Depending on the operational conditions, the vessel models may briefly be classified into stationkeeping, low-velocity, and high-velocity models. As shown in Sørensen (2011) and Fossen (2011) and the references therein, different model reduction techniques are used for the various speed regimes. Vessel motions in waves are defined as seakeeping and will here apply both for stationkeeping (zero speed) and forward speed. DP vessels or PM vessels can in general be regarded as stationkeeping and low-velocity or low Froude number applications. This assumption will particularly be used in the formulation of mathematical models used in conjunction with the controller design. It is common to use a two-time scale formulation by separating the total model into a low-frequency (LF) model and a wave-frequency (WF) model (seakeeping) by superposition. Hence, the total motion is a sum of the corresponding LF and the WF components. The WF motions are assumed to be caused by first-order wave loads. Assuming small amplitudes, these motions will be well represented by a linear model. The LF motions are assumed to be caused by second-order mean and slowly varying wave loads, current loads, wind loads, mooring (if any), and thrust and rudder forces and moments.

For underwater vehicles operating below the wave zone, estimated to be deeper than half the wavelength, the wave loads can be disregarded and of course the effect of the wind loads as well.

Modeling Issues

The mathematical models may be formulated in two complexity levels:

- *Control plant model* is a simplified mathematical description containing only the main physical properties of the process or plant. This model may constitute a part of the controller. The control plant model is also used in analytical stability analysis based on, e.g., Lyapunov stability.

- *Process plant model* or simulation model is a comprehensive description of the actual process and should be as detailed as needed. The main purpose of this model is to simulate the real plant dynamics. The process plant model is used in numerical performance and robustness analysis and testing of the control systems. As shown above, the process plant models may be implemented for off-line or real-time simulation (e.g., HIL testing; see Johansen et al. 2007) purposes defining different requirements for model fidelity.

Kinematics

The relationship between the Earth-fixed position and orientation of a floating structure and its body-fixed velocities is

$$\dot{\boldsymbol{\eta}} = \begin{bmatrix} \dot{\boldsymbol{\eta}}_1 \\ \dot{\boldsymbol{\eta}}_2 \end{bmatrix} = \begin{bmatrix} \mathbf{J}_1(\boldsymbol{\eta}_2) & \mathbf{0}_{3 \times 3} \\ \mathbf{0}_{3 \times 3} & \mathbf{J}_2(\boldsymbol{\eta}_2) \end{bmatrix} \begin{bmatrix} \mathbf{v}_1 \\ \mathbf{v}_2 \end{bmatrix} \quad (1)$$

The vectors defining the Earth-fixed vessel position ($\boldsymbol{\eta}_1$) and orientation ($\boldsymbol{\eta}_2$) using Euler angles and the body-fixed translation ($\mathbf{v}_1$) and rotation ($\mathbf{v}_2$) velocities are given by

$$\boldsymbol{\eta}_1 = [x \ y \ z]^T, \boldsymbol{\eta}_2 = [\phi \ \theta \ \psi]^T, \\ \mathbf{v}_1 = [u \ v \ w]^T, \mathbf{v}_2 = [p \ q \ r]^T. \quad (2)$$

The rotation matrix $\mathbf{J}_1(\boldsymbol{\eta}_2) \in \mathbf{SO}(3)$ and the velocity transformation matrix $\mathbf{J}_2(\boldsymbol{\eta}_2) \in \mathbb{R}^{3 \times 3}$ are defined in Fossen (2011). For ships, if only surge, sway and yaw (3DOF) are considered, the kinematics and the state vectors are reduced to

$$\dot{\boldsymbol{\eta}} = \mathbf{R}(\psi)\mathbf{v}, \text{ or } \begin{bmatrix} \dot{x} \\ \dot{y} \\ \dot{\psi} \end{bmatrix} \\ = \begin{bmatrix} \cos \psi & -\sin \psi & 0 \\ \sin \psi & \cos \psi & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} u \\ v \\ r \end{bmatrix}. \quad (3)$$

Process Plant Model: Low-Frequency Motion

The 6-DOF LF model formulation is based on Fossen (2011) and Sørensen (2011). The

equations of motion for the nonlinear LF model of a floating vessel are given by

$$\mathbf{M}\dot{\mathbf{v}} + \mathbf{C}_{RB}(\mathbf{v})\mathbf{v} + \mathbf{C}_A(\mathbf{v}_r)\mathbf{v}_r + \mathbf{D}(\mathbf{v}_r) + \mathbf{G}(\boldsymbol{\eta}) \\ = \boldsymbol{\tau}_{\text{wave2}} + \boldsymbol{\tau}_{\text{wind}} + \boldsymbol{\tau}_{\text{thr}} + \boldsymbol{\tau}_{\text{moor}}, \quad (4)$$

where $\mathbf{M} \in \mathbb{R}^{6 \times 6}$ is the system inertia matrix including added mass; $\mathbf{C}_{RB}(\mathbf{v}) \in \mathbb{R}^{6 \times 6}$ and $\mathbf{C}_A(\mathbf{v}_r) \in \mathbb{R}^{6 \times 6}$ are the skew-symmetric Coriolis and centripetal matrices of the rigid body and the added mass; $\mathbf{G}(\boldsymbol{\eta}) \in \mathbb{R}^6$ is the generalized restoring vector caused by the mooring lines (if any), buoyancy, and gravitation; $\boldsymbol{\tau}_{\text{thr}} \in \mathbb{R}^6$ is the control vector consisting of forces and moments produced by the thruster system; $\boldsymbol{\tau}_{\text{wind}}$ and $\boldsymbol{\tau}_{\text{wave2}} \in \mathbb{R}^6$ are the wind and second-order wave load vectors, respectively.

The damping vector may be divided into linear and nonlinear terms according to

$$\mathbf{D}(\mathbf{v}_r) = \mathbf{d}_L(\mathbf{v}_r, \kappa)\mathbf{v}_r + \mathbf{d}_{NL}(\mathbf{v}_r, \gamma_r)\mathbf{v}_r, \quad (5)$$

where $\mathbf{v}_r \in \mathbb{R}^6$ is the relative velocity vector between the current and the vessel. The nonlinear damping, $\mathbf{d}_{NL}$, is assumed to be caused by turbulent skin friction and viscous eddy-making, also denoted as vortex shedding (Faltinsen 1990). The strictly positive linear damping matrix $\mathbf{d}_L \in \mathbb{R}^{6 \times 6}$ is caused by linear laminar skin friction and is assumed to vanish for increasing speed according to

$$\mathbf{d}_L(\mathbf{v}_r, \kappa) = \begin{bmatrix} X_{u_r} e^{-\kappa|u_r|} & .. & X_r e^{-\kappa|r|} \\ .. & .. & .. \\ N_{u_r} e^{-\kappa|u_r|} & .. & N_r e^{-\kappa|r|} \end{bmatrix}, \quad (6)$$

where κ is a positive scaling constant such that $\kappa \in \mathbb{R}^+$.

Process Plant Model: Wave-Frequency Motion

The coupled equations of the WF motions in surge, sway, heave, roll, pitch, and yaw are assumed to be linear and can be formulated as

$$\begin{aligned} \mathbf{M}(\omega)\dot{\boldsymbol{\eta}}_{Rw} + \mathbf{D}_p(\omega)\dot{\boldsymbol{\eta}}_{Rw} + \mathbf{G}\boldsymbol{\eta}_{Rw} &= \boldsymbol{\tau}_{\text{wave1}}, & \dot{\omega}_p &= 0, & (12) \\ \dot{\boldsymbol{\eta}}_w &= \mathbf{J}(\bar{\boldsymbol{\eta}}_2)\dot{\boldsymbol{\eta}}_{Rw}, & \mathbf{y} &= \left[(\boldsymbol{\eta} + \mathbf{C}_{pw}\mathbf{p}_w)^T \quad \omega_p \right]^T, & (13) \end{aligned} \quad (7)$$

where $\boldsymbol{\eta}_{Rw} \in \mathbb{R}^6$ is the WF motion vector in the hydrodynamics frame. $\boldsymbol{\eta}_w \in \mathbb{R}^6$ is the WF motion vector in the Earth-fixed frame. $\boldsymbol{\tau}_{\text{wave1}} \in \mathbb{R}^6$ is the first-order wave excitation vector, which will be modified for varying vessel headings relative to the incident wave direction. $\mathbf{M}(\omega) \in \mathbb{R}^{6 \times 6}$ is the system inertia matrix containing frequency dependent added mass coefficients in addition to the vessel's mass and moment of inertia. $\mathbf{D}_p(\omega) \in \mathbb{R}^{6 \times 6}$ is the wave radiation (potential) damping matrix. The linearized restoring coefficient matrix $\mathbf{G} \in \mathbb{R}^{6 \times 6}$ is due to gravity and buoyancy affecting heave, roll, and pitch only. For anchored vessels, it is assumed that the mooring system will not influence the WF motions.

Remark 1 Generally, a time domain equation cannot be expressed with frequency domain coefficient $-\omega$. However, this is a common used formulation denoted as a pseudo-differential equation. An important feature of the added mass terms and the wave radiation damping terms is the memory effects, which in particular are important to consider for nonstationary cases, e.g., rapid changes of heading angle. Memory effects can be taken into account by introducing a convolution integral or a so-called retardation function (Newman 1977) or state space models as suggested by Fossen (2011).

Control Plant Model

For the purpose of controller design and analysis, it is convenient to apply model reduction and derive a LF and WF control plant model in surge, sway, and yaw about zero vessel velocity according to

$$\dot{\mathbf{p}}_w = \mathbf{A}_{pw}\mathbf{p}_w + \mathbf{E}_{pw}\mathbf{w}_{pw}, \quad (8)$$

$$\dot{\boldsymbol{\eta}} = \mathbf{R}(\psi)\mathbf{v}, \quad (9)$$

$$\dot{\mathbf{b}} = -\mathbf{T}_b\mathbf{b} + \mathbf{E}_b\mathbf{w}_b, \quad (10)$$

$$\mathbf{M}\dot{\mathbf{v}} = -\mathbf{D}_L\mathbf{v} + \mathbf{R}^T(\psi)\mathbf{b} + \boldsymbol{\tau}, \quad (11)$$

where $\omega_p \in \mathbb{R}$ is the peak frequency of the waves (PFW). The estimated PFW can be calculated by spectral analysis of the pitch and roll measurements assumed to dominantly oscillate at the peak wave frequency. In the spectral analysis, the discrete Fourier transforms of the measured roll and pitch, which are collected through a period of time, are done by taking the n-point fast Fourier transform (FFT). The PFW may be found to be the frequency at which the power spectrum is maximal. The assumption $\dot{\omega}_p = 0$ is valid for slowly varying sea state. You can also find the wave frequency using nonlinear observers/EKF and signal processing techniques. It is assumed that the second-order linear model is sufficient to describe the first-order wave-induced motions, and then $\mathbf{p}_w \in \mathbb{R}^6$ is the state of the WF model. $\mathbf{A}_{pw} \in \mathbb{R}^{6 \times 6}$ is assumed Hurwitz and describes the first-order wave-induced motion as a mass-damper-spring system. $\mathbf{w}_{pw} \in \mathbb{R}^3$ is a zero-mean Gaussian white noise vector. $\mathbf{y}$ is the measurement vector. The WF measurement matrix $\mathbf{C}_{pw} \in \mathbb{R}^{3 \times 6}$ and the disturbance matrix $\mathbf{E}_{pw} \in \mathbb{R}^{6 \times 3}$ are formulated as

$$\mathbf{C}_{pw} = [\mathbf{0}_{3 \times 3} \quad \mathbf{I}_{3 \times 3}], \mathbf{E}_{pw}^T = [\mathbf{0}_{3 \times 3} \quad \mathbf{K}_w^T]^T. \quad (14)$$

Here, a 3-DOF model is assumed adopting the notation in (3) such that $\boldsymbol{\eta} \in \mathbb{R}^3$ and $\mathbf{v} \in \mathbb{R}^3$ are the LF position vector in the Earth-fixed frame and the LF velocity vector in the body-fixed frame, respectively. $\mathbf{M} \in \mathbb{R}^{3 \times 3}$ and $\mathbf{D}_L \in \mathbb{R}^{3 \times 3}$ are the mass matrix including hydrodynamic added mass and linear damping matrix, respectively. The bias term accounting for unmodeled affects and slowly varying disturbances $\mathbf{b} \in \mathbb{R}^3$ is modeled as Markov processes with positive definite diagonal matrix $\mathbf{T}_b \in \mathbb{R}^{3 \times 3}$ of time constants. If $\mathbf{T}_b$ is removed, a Wiener process is used. $\mathbf{w}_b \in \mathbb{R}^3$ is a bounded disturbance vector, and $\mathbf{E}_b \in \mathbb{R}^{3 \times 3}$ is a disturbance scaling matrix. $\boldsymbol{\tau} \in \mathbb{R}^3$

is the control force. As mentioned later in the paper, the proposed model reduction considering only horizontal motions may create problems conducting DP operations of structures with low waterplane area such as semisubmersibles. More details can be found in Sørensen (2011) and Fossen (2011) and the references therein.

For underwater vehicles, 6-DOF model should be used. For underwater vehicles with self-stabilizing roll and pitch, a 4-DOF model with surge, sway, yaw, and heave may be used; see Sørensen et al. (2012).

Control Levels and Integration Aspects

The real-time control hierarchy of a marine control system (Sørensen 2005) may be divided into three levels: *the guidance system and local optimization*, *the high-level plant control* (e.g., DP controller including thrust allocation), and *the low-level thruster control*. The DP control system consists of several modules as indicated in Fig. 1:

- *Signal processing* for analysis and testing of the individual signals including voting and weighting when redundant measurements are available. Ensuring robust and fault-tolerant control proper diagnostics and change detection algorithms is regarded as maybe one of the most important research areas. For an overview of the field, see Basseville and Nikiforov (1993) and Blanke et al. (2003).
- *Vessel observer* for state estimation and wave filtering. In case of lost sensor signals, the predictor is used to provide dead reckoning, which is required by class societies. Prediction error which is the deviation between the measurements and the estimated measurements is also one important barrier in the failure detection.
- *Feedback control law* is often of multivariable PID type, where feedback is produced from the estimated low-frequency (LF) position and heading deviations and estimated LF velocities.

- *Feedforward control law* is normally the wind force and moment. For the different applications (pipe laying, ice operations, position mooring), tailor-made feedforward control functions are also used.
- *Guidance system with reference models* is needed in achieving a smooth transition between setpoints. In the most basic case, the operator specifies a new desired position and heading, and a reference model generates smooth reference trajectories/paths for the vessel to follow. A more advanced guidance system involves way-point tracking functionality with optimal path planning.
- *Thrust allocation* computes the force and direction commands to each thruster device based on input from the resulting feedback and feedforward controllers. The low-level thruster controllers will then control the propeller pitch, speed, torque, and power.
- *Model adaptation* provides the necessary corrections of the vessel model and the controller settings subject to changes in the vessel draft, wind area, and variations in the sea state.
- *Power management system* performs diesel engine control, power generation management with frequency and voltage monitoring, active and passive load sharing, and load dependent start and stop of generator sets.

DP Controller

In the 1960s the first DP system was introduced for horizontal modes of motion (surge, sway, and yaw) using single-input single-output PID control algorithms in combination with low-pass and/or notch filters. In the 1970s more advanced output control methods based on multivariable optimal control and Kalman filter theory were proposed by Balchen et al. (1976) and later refined in Sælid et al. (1983); Grimble and Johnson (1988); and others as referred to in Sørensen (2011). In the 1990s nonlinear DP controller designs were proposed by several research groups; for an overview see Strand et al. (1998), Fossen and Strand (1999), Pettersen and Fossen (2000), and Sørensen (2011). Nguyen et al. (2007) proposed

Dynamic Positioning Control Systems for Ships and Underwater Vehicles, Fig. 1 Controller structure

the design of hybrid controller for DP from calm to extreme sea conditions.

Plant Control

By copying the control plant model (8)–(13) and adding an injection term, a passive observer may be designed. A nonlinear output horizontal-plane positioning feedback controller of PID type may be formulated as

$$\tau_{PID} = -\mathbf{R}_e^T \mathbf{K}_p \mathbf{e} - \mathbf{R}_e^T \mathbf{K}_{p3} \mathbf{f}(\mathbf{e}) - \mathbf{K}_d \tilde{\mathbf{v}} - \mathbf{R}^T \mathbf{K}_i \mathbf{z}, \quad (15)$$

where $\mathbf{e} \in \mathbb{R}^3$ is the position and heading deviation vector, $\tilde{\mathbf{v}} \in \mathbb{R}^3$ is the velocity deviation vector, $\mathbf{z} \in \mathbb{R}^3$ is the integrator states, and $\mathbf{f}(\mathbf{e})$ is a third-order stiffness term defined as

$$\mathbf{e} = [e_1, e_2, e_3]^T = \mathbf{R}^T(\phi_d)(\hat{\boldsymbol{\eta}} - \boldsymbol{\eta}_d),$$

$$\tilde{\mathbf{v}} = \hat{\mathbf{v}} - \mathbf{R}^T(\phi_d)\boldsymbol{\eta}_d,$$

$$\dot{\mathbf{z}} = \hat{\boldsymbol{\eta}} - \boldsymbol{\eta}_d,$$

$$\mathbf{R}_e = \mathbf{R}(\phi - \phi_d) = \mathbf{R}^T(\phi_d)\mathbf{R}(\phi),$$

$$\mathbf{f}(\mathbf{e}) = [e_1^3, e_2^3, e_3^3]^T.$$

Experience from implementation and operations of real DP control systems has shown that ϕ_d in the calculation of the error vector $\mathbf{e}$ generally gives a better performance with less noisy signals than using ϕ . However, this is only valid under the assumption that the vessel maintains its desired heading with small deviations. As the DP capability for ships is sensitive to the heading angle, i.e., minimizing the environmental loads, heading control is prioritized in case of limitations in the thrust capacity. This feature is handled in the thrust allocation.

An advantage of this is the possibility to reduce the first-order proportional gain matrix, resulting in reduced dynamic thruster action for smaller position and heading deviations. Moreover, the third-order restoring term will make the thrusters to work more aggressive for larger deviations. $\mathbf{K}_p$, $\mathbf{K}_{p3}$, $\mathbf{K}_d$, and $\mathbf{K}_i \in \mathbb{R}^{3 \times 3}$ are the nonnegative controller gain matrices for proportional, third-order restoring,

Dynamic Positioning Control Systems for Ships and Underwater Vehicles, Fig. 2 Thrust allocation

derivative, and integrator controller terms, respectively, found by appropriate controller synthesis methods.

For small-waterplane-area marine vessels such as semisubmersibles, often used as drilling rigs, Sørensen and Strand (2000) proposed a DP control law with the inclusion of roll and pitch damping according to

$$\tau_{rpd} = - \begin{bmatrix} 0 & g_{xq} \\ g_{yp} & 0 \\ g_{\phi p} & 0 \end{bmatrix} \begin{bmatrix} \hat{p} \\ \hat{q} \end{bmatrix}, \quad (16)$$

where $\hat{p}$ and $\hat{q}$ are the estimated pitch and roll angular velocities. The resulting positioning control law is written as

$$\tau = \tau_{wff} + \tau_{PID} + \tau_{rpd}, \quad (17)$$

where $\tau_{wff} \in \mathbb{R}^3$ is the wind feedforward control law.

Thrust allocation or control allocation (Fig. 2) is the mapping between plant and actuator control. It is assumed to be a part of the plant control. The DP controller calculated the desired force in surge and sway and moment in yaw. Dependent on the particular thrust configuration with installed and enabled propellers, tunnel thrusters, azimuthing thrusters, and rudders, the allocation

is a nontrivial optimization problem calculating the desired thrust and direction for each enabled thruster subject to various constraints such as thruster ratings, forbidden sectors, and thrust efficiency. References on thrust allocation are found in Johansen and Fossen (2013).

In Sørensen and Smogeli (2009), torque and power control of electrically driven marine propellers are shown. Ruth et al. (2009) proposed anti-spin thrust allocation, and Smogeli et al. (2008) and Smogeli and Sørensen (2009) presented the concept of anti-spin thruster control.

Abstract

The classical field of social network analysis (SNA) considers societies and social groups as *networks*, assembled of social actors (individuals, groups or organizations) and relationships among them, or social ties. From the systems and control perspective, a social network may be considered as a complex dynamical system where an actor's attitudes, beliefs, and behaviors related to them evolve under the influence of the other actors. As a result of these local interactions, complex dynamical behaviors arise that depend on both individual characteristics of actors and the structural properties of a network. This entry provides basic concepts and theoretical tools elaborated to study dynamical social networks. We focus

on (a) structural properties of networks and (b) dynamical processes over them, e.g., dynamics of opinion formation.

Keywords

Social network · Dynamical network ·
Centrality measure · Opinion formation

Introduction

Pioneer works of Moreno and Jennings (1938) have opened up a new interdisciplinary field of study, which is nowadays called social network analysis (SNA) (Freeman 2004). SNA has anticipated and inspired, to a great extent, the general theory of complex networks (Newman 2003) developed in the recent decades. Many important structural properties of networks, e.g., centrality measures, cliques, and communities, have arisen as characteristics of social groups and have been studied from a sociological perspective (Freeman 2004). On a parallel line of research, *dynamics* over social networks have been studied that are usually considered as processes of information diffusion over networks (Del Vicario et al. 2016; Arnaboldi et al. 2016) and evolution of individual opinions, attitudes, beliefs, and actions related to them under social influence (Friedkin 2015; Proskurnikov and Tempo 2017, 2018).

The theory of dynamical social networks (DSNs) combines the two aforementioned lines of research and considers a social network as a dynamical system, aiming at understanding the interplay between the network's structural properties and behaviors of dynamical processes over the network. The ultimate and long-standing goal is to develop the theory of *temporal* social networks, where both vertices (standing for social actors) and edges (standing for social relations) can emerge and disappear.

In this entry, we provide a brief overview of the main concepts and tools, related to the theory of DSN, focusing on its system- and control-theoretic aspects.

Mathematical Representation of a Social Network

Mathematically, a social network is naturally represented by a directed *graph*, that is, a pair $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ constituted by a finite set of *nodes* (or *vertices*) $\mathcal{V}$ and a set of (directed) *arcs* (or *edges*) $\mathcal{E}$ (Fig. 1). The nodes represent social actors (individuals or organizations), and the arcs stand for relations (influence, dependence, similarity, etc.).

The structure of arcs can be encoded by the adjacency matrix $A = (a_{ij})$, whose entry is $a_{uv} = 1$ if $(u, v) \in \mathcal{E}$ and $a_{uv} = 0$ otherwise. More generally, it is often convenient to assign heterogeneous *weights* to the arcs that can quantify the relations' strengths (Liu 2012). In this case, a *weighted* adjacency matrix $W = (w_{ij})$ is introduced, where $w_{uv} \neq 0$ if and only if $(u, v) \in \mathcal{E}$. A triple $(\mathcal{V}, \mathcal{E}, W)$ is referred to as a *weighted* (or *valued*) graph. In some problems (e.g., structural balance theory (Cartwright and Harary 1956; Marvel et al. 2011; Facchetti et al. 2011)), it is convenient to distinguish positive and negative relationships (trust/distrust, friendship/enmity, cooperation/competition, etc.) assigning thus positive and negative weights to the arcs; such a graph is said to be *signed*.

Structural Properties of Social Networks

At the dawn of SNA, it was realized that a social group is more than a sum of individual actors and cannot be examined apart from the structure of social relationships or *ties*. Numerous characteristics have been proposed in the literature to

Dynamical Social Networks, Fig. 1 Example of a directed graph with six nodes: $\mathcal{V} = \{1, \dots, 6\}$ and $\mathcal{E} = \{(1, 2), (1, 4), (2, 1), (2, 3), (3, 2), (3, 4), (3, 6), (4, 3), (4, 5), (4, 6), (5, 6), (6, 4), (6, 5)\}$

quantify the structure of social ties and social actors' positions within a network. Many of these characteristics prove to be useful in analysis of general large-scale networks (Newman 2003).

Density Characteristics

Many large-scale social networks are *sparse* in the sense that the number of the (directed) arcs is much smaller than the maximal possible number n^2 , where $n = |\mathcal{V}|$ is the number of nodes (also referred to as the network size). See, e.g., SNAP dataset collection (Leskovec and Sosič 2016) and The Colorado Index of Complex Networks at <https://icon.colorado.edu/#!/networks>. These social networks can be easily visualized using the software GraphViz (Ellson et al. 2001) or Gephi <https://gephi.org/users/download/>. Another example (Bokuniewicz and Shulman 2017) is the structure of Twitter networks of marketing organizations with a very sparse adjacency matrix. A natural coefficient to quantify the network's sparsity property is the *network density* $\rho = |\mathcal{E}|/n^2$.

Another way to quantify the sparsity of the network is to consider the *degree* of a node. If, from sociological perspective, an agent is influenced from few friends, then the in-degree, i.e., the number of edges incoming to a specific node, is low compared to the size of the network. As a consequence, the corresponding row in the adjacency matrix is sparse, i.e., with few nonzero elements. Many real-world networks are "scale-free" networks (Newman 2003) with a degree distribution of the form $p(k) \propto k^{-\gamma}$ with $\gamma \in (2, 3)$ (here $p(k)$ is the proportion of nodes having in-degree $k = 0, 1, 2, \dots$); it is remarkable that similar distributions were discovered in the early works on sociometry (Moreno and Jennings 1938).

Many social networks are featured by the presence of few clusters or *communities* (Arnaboldi et al. 2016; Newman 2003). Social actors within a community are densely connected, whereas relationships between different communities are sparse. These types of networks are described by an influence matrix that can be decomposed as a sum of a low-rank matrix and a sparse matrix. The sparseness, scale-freeness, and clus-

tering are common properties that are regularly exploited in data storage (Tran 2012), reconstruction of influence networks (Ravazzi et al. 2018), and identification of communities in large-scale social networks (Blondel et al. 2008). Sparsity is also related to structural controllability (Liu et al. 2011): in some sense, sparse networks are the most difficult to control, whereas dense networks can be controlled via a few driver nodes.

Centrality Measures, Resilience, and Structural Controllability

The problem of identifying the most "important" (influential) nodes in the social network dates back to the first works on sociometry in the 1930s. At a "local" level, the influence of a node can be measured by its degree, that is, the number of social actors influenced by the corresponding individuals. However, a person that is influential within his/her small community need not be a global opinion leader. To distinguish globally influential nodes, various *centrality measures* have been introduced (Friedkin 1991; Freeman 2004; Newman 2003), among which the most important are *closeness*, *betweenness*, and *eigenvector centralities*.

In a connected network, the closeness centrality relates to how long it will take to spread information from a node u to all other nodes in the network. Mathematically,

$$c_u = \frac{1}{\sum_{v \in \mathcal{V} \setminus \{u\}} d_{uv}}, \quad \forall u \in \mathcal{V}.$$

where d_{uv} is the length of the shortest path between u and v .

Betweenness of node u (Freeman 1977) is defined as

$$b_u = \sum_{j, k \in \mathcal{V}, j \neq k \neq u} \frac{|S_u(j, k)|}{|S(j, k)|}$$

where $S(j, k)$ denotes the set of shortest paths from j to k and $S_u(j, k)$ the set of shortest paths from j to k that contain the node u . Hence, the more shortest paths pass through node u , the higher is its betweenness. Similarly, the *edge betweenness* can be introduced (Newman

2003) that measures the number of shortest paths containing an edge. Nodes and edges of high betweenness serve as “bridges” between other nodes.

Eigenvector centrality measures the influence of an individual in a social network by means of the leading eigenvector π^* of a suitable weighted adjacency matrix M , i.e., the scores of the nodes π_u^* are found from the equations

$$\pi_u^* = \frac{1}{\lambda} \sum_{v \in \mathcal{V}} M_{uv} \pi_v^* \quad (1)$$

where λ is the leading eigenvalue of M . This idea leads to Bonacich, Katz, and Freeman centrality measures (Friedkin 1991) and the PageRank (Brin and Page 1998). The main principle of eigenvector centrality is to assign high scores to nodes whose neighbors are highly ranked.

In particular, PageRank is computed as in (1) defining

$$M = (1 - m)A + \frac{m}{n} \mathbf{1}\mathbf{1}^\top,$$

where m is a scalar parameter, usually set to 0.15, n is the graph’s size and A is the adjacency matrix of a graph renormalized to be row stochastic (i.e., $a_{ij} = 1/d_i$ if i and j are connected, where d_i stands for the degree of node i).

Considering the simple graph in Fig. 1, it should be noticed that different centrality measures may produce very different ranking (see Tables 1 and 2).

Identification of the most influential nodes may be also considered as an analysis of network’s *resilience* properties, that is, its ability

Dynamical Social Networks, Table 1 Centrality measures of nodes in the graph of Fig. 1

Node	Out-degree	Closeness	Betweenness	PageRank
1	2	15	0.833	0.061
2	2	11	0.5	0.085
3	3	9	2.166	0.122
4	3	7	3.666	0.214
5	1	9	0	0.214
6	2	7	0.5	0.302

Dynamical Social Networks, Table 2 Ranking of nodes in the graph of Fig. 1 according to different centrality measures

Centrality measure	Ranking
Degree	(3,4,1,2,6,5)
Closeness	(1,2,3,5,4,6)
Betweenness	(4,3,1,2,6,5)
PageRank	(6,4,5,3,2,1)

to counteract various malicious attacks. This problem is especially important in online social media where attacks on the “most central” nodes allow to disseminate fake news, rumors, and other sorts of disinformation. At the same time, users of such media can manipulate their ranks (e.g., by adding fictitious profiles and/or connections), which leads to another important problem: how does the PageRank change under perturbations of a network, e.g., how large values of the rank can one obtain by activating some “hidden” links (Csáji et al. 2014). As has been shown in Como and Fagnani (2015), families of graphs with “fast-mixing” properties, such as expander graphs, are more resilient to localized perturbations than “slow-mixing” ones that exhibit information diffusion bottlenecks. The mixing-time properties of graphs are related to robustness of stochastic matrices against perturbations (Como and Fagnani 2015).

The aforementioned resilience problems are closely related to a problem of *controlling* centrality measures in *weighted graphs*, addressed in Nicosia et al. (2012). It has been shown that a relatively small “control set” of nodes can produce an *arbitrary* centrality vector by assigning influence weights to their neighbors. To compute the minimal controlling set is a difficult problem, reducing to the NP-hard problem of identifying the minimal *dominating set* in the graph, that is, the set of nodes such that any node is either dominating or adjacent to at least one dominating node (Fig. 2).

Dynamical Social Networks, Fig. 2 The minimal dominating set $S = \{3, 4\}$ of two nodes

Structural Balance in Signed Networks

Structural balance is an important property of a social network with signed weights on the arcs, standing for positive and negative relations among individuals (trust/distrust, cooperation/competition, friendship/enmity, etc.). The concept of structural balance originates from the works of Heider (1946), further developed by Cartwright and Harary (1956). As Heider argued (Heider 1946), “an attitude towards an event can alter the attitude towards the person who caused the event, and, if the attitudes towards a person and an event are similar, the event is easily ascribed to the person.” The same applies to attitudes toward people and other objects. Heider’s theory predicts the emergence of a *balanced* state where positive and negative relations among individuals are in harmony with their attitudes to people, things, ideas, situations, etc. If actor *A* likes actor *B* in the balanced state, then *A* shares with *B* a positive or negative appraisal of any other individual *C*; vice versa, if *A* dislikes *B*, then *A* disagrees with any *B*’s appraisal of *C*.

In other words, if a social network corresponds to a complete signed graphs where each actor has a positive or negative appraisal of all other actors, then it tends to a balanced state satisfying four simple axioms (Fig. 3):

1. A friend of my friend is my friend.
2. A friend of my enemy is my enemy.
3. An enemy of my friend is my enemy.
4. An enemy of my enemy is my friend.

Dynamical Social Networks, Fig. 3 Balanced (left) vs. imbalanced (right) triads

The violation of these rules leads to tensions and cognitive dissonances that have to be somehow resolved; the description of such tension resolving mechanisms is beyond Heider’s theory, and their mathematical modeling is a topic of ongoing research.

If the signed complete graph is balanced, then its node can be divided into two opposing factions, where members of the same factions are “friends” and every two actors from different factions are “enemies” (if all relations are positive, then one of the factions is empty). This property can be used as a definition of the structural balance in a more general situation where the graph is not necessarily complete (Cartwright and Harary 1956); a strongly connected graph is decomposed into two opposing factions if and only if the product of signs along any path connecting two nodes *i* and *j* is the same and depends only on the pair (*i*, *j*) (equivalently, the product of all signs over a semicycle is positive). Experimental studies reveal that many large-scale networks are close to the balanced state (Facchetti et al. 2011).

Dynamical Processes over Social Networks

Spread of information (including fake news and rumors), evolution of attitudes, beliefs and actions related to them, and strengthening and weakening of social ties are examples of dynamic processes unfolding over social networks. In this entry, we give a brief overview of the most “mature” results on social dynamics obtained in the systems and control literature and the related mathematical concepts.

Opinions and Models of Opinion Formation

As discussed in Friedkin (2015), an individual’s opinion is his/her cognitive orientation toward some object, e.g., particular issue, event, action, or another person. Opinions can stand for displayed attitudes or subjective certainties of belief. Mathematically, opinions are usually modeled as either elements of a discrete set (e.g., the decision

to support some action to withstand it, the name of a presidential election candidate to vote for) or scalar and vector quantities, belonging to a subset of the Euclidean space.

One of the simplest models with discrete opinions is known as the *voter model* (Clifford and Sudbury 1973). Each node of a network is associated to an actor (“voter”) whose opinion is a binary value (0 or 1). At each step, a random voter is selected who replaces his/her opinion by the opinion of a randomly chosen neighbor in the graph. Other examples include, but are not limited to, Granovetter’s threshold model (Granovetter 1978) (an individual supports some action if some proportion of his/her neighbors support it), Schelling model or spatial segregation (Schelling 1971) (the graph stands for a network of geographic locations, and an opinion is the preferred node to live), Axelrod’s model of culture dissemination (Axelrod 1997) (an opinion stands for a set of cultural traits), and the Ising model of phase transition adapted to social behaviors (Sznajd-Weron and Sznajd 2000). The aforementioned models are usually examined by tools of advanced probability theory and statistical physics (Castellano et al. 2009).

Control-theoretic studies on opinion dynamics have primarily focused on models with real-valued (“continuous”) opinions, which can attain a continuum of values. We consider only microscopic or agent-based models of opinion formation, portraying evolution of individual opinions and described by systems of differential or recurrent equations, whose dimension is proportional to the size of the network (number of social actors). As the number of actors tends to infinity, the dynamics transforms into a macroscopic (statistical, Eulerian, fluid-based, mean-field) model that portrays the evolution of opinion *distribution* (a density function or a probability measure) and is usually described by a partial differential or integral equation (Canuto et al. 2012).

Models of Rational Consensus: Social Power

A simple model of opinion formation was proposed by French (1956), examined by Harary (1959), and generalized by DeGroot (1974) as

an iterative procedure to reach a consensus. Each social actor in a network keeps a scalar or vector opinion $x_i \in \mathbb{R}^d$ (e.g., a vector of subjective probabilities (DeGroot 1974; Wai et al. 2016)). At each stage of the opinion evolution, the opinions are simultaneously recalculated based on a simple rule of iterative averaging

$$x_i(t+1) = \sum_{j=1}^n w_{ij} x_j(t) \quad \forall i = 1, \dots, n, \quad t = 0, 1, \dots \quad (2)$$

Here n stands for the number of social actors, and $W = (w_{ij})$ is a stochastic (A $n \times n$ matrix W is (row-)stochastic if all its entries are nonnegative $w_{ij} \geq 0$, and each row sums up to 1, i.e., $\sum_{j=1}^n w_{ij} = 1$ for each $i = 1, \dots, n$.) matrix of *influence weights*. The matrix W should be compatible with the graph of a social network, that is, an actor allocates influence weight to the adjacent actors (including him/herself if the node has a self-arc). The influence can be thought of as a finite resource each individual distributes to self and the others (Friedkin 2015). In the original French’s model, this distribution is uniform: if a node has out-degree m , each neighboring node gets the weight $1/m$, e.g., the graph structure in Fig. 4 induces the following rule of opinion update (for simplicity, we assume that opinions are scalar)

$$\begin{bmatrix} x_1(t+1) \\ x_2(t+1) \\ x_3(t+1) \end{bmatrix} = \begin{pmatrix} 1/2 & 1/2 & 0 \\ 1/3 & 1/3 & 1/3 \\ 0 & 1/2 & 1/2 \end{pmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \\ x_3(t) \end{bmatrix}.$$

A continuous-time counterpart of model (2) was proposed by Abelson (1964)

Dynamical Social Networks, Fig. 4 An example of the French model with $n = 3$ agents

$$\dot{x}_i(t) = \sum_{j=1}^n a_{ij}(x_j(t) - x_i(t)), \quad i = 1, \dots, n, \\ t \geq 0. \quad (3)$$

The coefficients $a_{ij} \geq 0$ play the role of infinitesimal influence weights; the matrix $A = (a_{ij})$ is not necessarily stochastic yet should be compatible with the graph of the social network: $a_{ij} > 0$ if and only if $(i, j) \in \mathcal{E}$.

The most typical behavior of the French-DeGroot and the Abelson model is *consensus* of the opinions, that is, their convergence to a common value $x_i(t) \xrightarrow{t \rightarrow \infty} x_*$ that depends on the initial condition. For this reason, these dynamical systems are often referred to as the *consensus protocols* and have been thoroughly studied in the literature on multi-agent systems (see the survey in Proskurnikov and Tempo 2017, 2018); first consensus criteria have been found by Harary (1959) and Abelson (1964). Consensus is established, for instance, whenever the graph of the social network contains a globally reachable node, and, in the discrete-time case, this node has a self-arc.

It is remarkable, however, that the original goal of French's work was not concerned with consensus but rather aimed at finding numerical characteristics of *social power*, that is, an individual's capability to influence the group's ultimate decisions. The consensus is established in the French DeGroot model if and only if the matrix W has a unique left eigenvector p corresponding to eigenvalue 1 such that (stochastic matrices satisfying this property are known as fully regular or SIA (stochastic indecomposable aperiodic) matrices; such a matrix serves as a transition matrix of some regular (ergodic) Markov chains (Proskurnikov and Tempo 2017). The vector p is nonnegative in view of the Perron-Frobenius theorem and stands for the unique stationary distribution of the corresponding Markov chain.)

$$p^\top W = p^\top, \quad \sum_{i=1}^n p_i = 1.$$

Using (2), one shows that

$$\begin{aligned} \sum_i p_i x_i(k+1) &= \sum_j \left(\sum_i p_i w_{ij} \right) x_j(k) \\ &= \sum_j p_j x_j(k) = \sum_i p_i x_i(k) \\ &= \dots = \sum_i p_i x_i(0), \end{aligned}$$

and passing to the limit as $k \rightarrow \infty$, one finds the consensus value x_* as follows:

$$x_* = \left(\sum_i p_i \right) x_* = \sum_i p_i x_i(0).$$

The component p_i can be thus considered as the influence of actor i 's opinion on the final opinion of the group. This measure of influence, or *social power*, of an individual is similar to the eigenvector centrality (computed for the normalized adjacency matrix).

Most of the properties of the French-DeGroot models retain their validity in the case of asynchronous *gossip-based* communication (Fagnani and Zampieri 2008) where at each stage of the opinion iteration, two randomly chosen actors interact, whereas the remaining actors' opinions remain unchanged. A gossip-based model portrays spontaneous interactions between people in real life and can be considered as a model of opinion formation over a random temporal (time-varying) graph.

From Consensus of Opinions to Community Cleavage

Whereas the French-DeGroot and the Abelson model predict consensus, real social groups often exhibit disagreement and clustering of opinions, even when the graph is strongly connected. Thus a realistic dynamic model of opinion formation should be able to explain both consensus and disagreement and help to disclose conditions that prevent the individuals from reaching a consensus. To find such models is a long-standing challenging problem in mathematical sociology referred to as Abelson's "diversity puzzle" or the

problem of *community cleavage* (Friedkin 2015; Proskurnikov and Tempo 2017).

Most of the opinion cleavage models studied in control theory stem from the French-DeGroot and the Abelson models. The three main classes of such models are:

1. Models with stubborn individuals
2. Homophily-based (bounded confidence) models
3. Models with antagonistic interactions

Models with Stubborn Individuals

The **first** class of models explains disagreement by stubbornness or “zealotry” of some individuals who are resistant to opinion assimilation. In the French-DeGroot model (2), such an actor assigns the maximal weight $w_{ii} = 1$ to him/herself being unaffected by the others’ opinions ($w_{ij} = 0$ for $j \neq i$), so that his/her opinion remains unchanged $x_i(t+1) = x_i(t) = \dots = x_i(0)$. Similarly, in the Abelson model, a stubborn individual assigns zero influence weights $a_{ij} = 0$ to all individuals, so that $\dot{x}_i(t) \equiv 0$. In the presence of two or more stubborn actors with different opinions, there is no consensus in the group, and the opinions split into several clusters (in the generic situation, all steady opinions are different).

A natural extension of the French-DeGroot model with stubborn individuals is the Friedkin-Johnsen model (Friedkin 2015), being an important and indispensable part of the social influence network theory (SINT) (Friedkin and Johnsen 2011). In the Friedkin-Johnsen model, actors are allowed to be “partially” stubborn. Namely, along with the stochastic matrix of influence weights $W = (w_{ij})$, a set of *susceptibility* coefficients $0 \leq \lambda_{11}, \dots, \lambda_{nn} \leq 1$ (or, equivalently, a diagonal matrix $0 \leq \Lambda \leq I_n$) is introduced that measure how strong is the influence of the actor’s initial opinion on all subsequent opinions:

$$x_i(t+1) = \lambda_{ii} \sum_j w_{ij} x_j(t) + (1 - \lambda_{ii}) x_i(0),$$

$$\forall i = 1, \dots, n \quad \forall t = 0, 1, \dots$$

The French-DeGroot model appears as a special case of the Friedkin-Johnsen system where none of the actors is anchored at his/her initial opinion ($\lambda_{ii} = 1$ for all i). If $\lambda_{ii} < 1$ for some i , then the matrix AW is typically Schur stable (has the spectral radius < 1). Assuming for simplicity that the opinions $x_i(t)$ are scalars, the vector $x(t) = (x_1(t), \dots, x_n(t))^T$ they constitute converges to

$$x(\infty) = \lim_{t \rightarrow \infty} x(t) = Vx(0),$$

$$V = (I - AW)^{-1}(I - A).$$

The matrix V (“control matrix” (Friedkin 2015)) is stochastic, but its rows are different. The average steady opinion of the group is thus found as

$$\frac{1}{n} \sum_{j=1}^n x_j(\infty) = \sum_j c_j x_j(0), \quad c_j = \frac{1}{n} \sum_{i=1}^n v_{ij}.$$

The vector $c = (c_1, \dots, c_n)$ is a natural generalization of French’s social power and measures the influence of the actors’ initial opinions on the average opinion of the group; it can thus also be thought of as a centrality measure. As discussed in Proskurnikov and Tempo (2017), in the case where $\Lambda = \alpha I$, $\alpha \in (0, 1)$, this centrality measure (first introduced in Friedkin 1991) is nothing else than the conventional PageRank.

Homophily-Based Models

The principle of homophily can be formulated as “birds of a feather fly together” (McPherson et al. 2001). Social actors tend to interact with like-minded individuals and assimilate their opinions easier than an opinion of a dissimilar person. This principle is prominently illustrated by models of bounded confidence, similar to the French-DeGroot and the Abelson model yet allowing the matrix (w_{ij}) (respectively, (a_{ij})) to depend on the system’s state. The Hegselmann-Krause model (Hegselmann and Krause 2002) is an extension of (2), stipulating that $w_{ij}(x_i, x_j) = 0$ if $|x_i - x_j| \geq \varepsilon$, where $\varepsilon > 0$ is an actor’s *confidence bound*. A gossip-based version of this model is due to Deffuant et al. (2000). A detailed discussion of bounded confidence models

(which, e.g., may contain partially stubborn individuals) and their convergence properties is available at the survey (Proskurnikov and Tempo 2018).

Antagonistic Interactions

Abelson (1964) suggested that one of the reasons for disagreement can be “boomerang” (reactance, anticonformity) effect: an attempt to convince other people can make them to adopt an opposing position. In other words, social actors do not always bring their opinions closer, and the convex-combination mechanisms of the models (2), (3) have to be generalized to allow repulsion between their opinions. This idea is in harmony with Heider’s theory of structural balance, predicting that individuals disliking each other should have opposite positions on every issue. Although the presence of negative ties in opinion formation models has not been secured experimentally, the mathematical theory of networks with positive and negative ties is important since such networks arise in abundance in biology and economics.

A natural extension of the French-DeGroot model allowing negative ties is known as the “discrete-time Altafini model” (Liu et al. 2017) (historically, its continuous-time counterpart was first proposed by Altafini; see the survey in Shi et al. (2019)) and deals with a system (2), where the weights w_{ij} can be positive and negative; however, their absolute values constitute a stochastic matrix ($|w_{ij}|$). It appears that a structurally balanced graph leads to bimodal polarization (or bipartite consensus) of the opinions: the actors in the two opposing factions converge on the two opposite opinions x_* and $(-x_*)$, where x_* depends on the initial opinion distribution. An imbalanced strongly connected graph induces, however, a degenerate behavior where all opinions converge to 0. In both situations, the opinions remain bounded. More sophisticated dynamic models have been proposed recently (Shi et al. 2019) that are able to explain clustering of opinions over graphs without structural balance property.

Inference of Networks’ Structures from Opinion Dynamics

Data-driven inference of a network’s characteristics using observations of some dynamical processes over the network is a topic of an active research in statistics, physics, and signal processing. In social networks, a natural dynamical process is opinion formation, which, as has been already mentioned, is closely related to centrality measures and other structural properties of a social graph.

The existing works on identification of opinion formation processes are primarily focused on linear models such as the French-DeGroot model (Wai et al. 2016) or the Friedkin-Johnsen model and its extensions (Ravazzi et al. 2018). Two different methods to infer the network’s structure are the *finite-horizon* and the *infinite horizon* identification procedures. In the finite-horizon approach, the opinions are observed for T subsequent rounds of conversation. Then, if enough observations are available, the parameters of the model (e.g., the matrix of influence weights $W = (w_{ij})$) can be estimated as the matrix best fitting the dynamics for $0 \leq k \leq T$, by using classical identification techniques.

The infinite-horizon approach, instead, performs the estimation based on the observations of the initial and final opinions’ profiles. One of the first works on the inference of the network topology is Wai et al. (2016), in which the authors consider French-DeGroot models with stubborn agents. This identification procedure has been adopted also in Ravazzi et al. (2018) to estimate the influence matrix of the Friedkin-Johnsen model, under the assumption that the matrix is sparse (i.e., agents are influenced by few friends). In these works, the estimation problem is non-convex, and deterministic or stochastic relaxation techniques are used to approximate it by semidefinite programs.

Dynamics of Social Graphs

Up to now, we have considered dynamics *over* social networks paying no attention to dynamics of networks themselves. Two examples where the network’s graph can be thought of as a temporal (time-varying) graphs are the aforementioned

models with gossip-based interactions (one may suppose that the graph of a network is random and contains a single arc at each step) and models with bounded confidence (if the opinions of two individuals are distant, the link connecting them may be considered as missing).

Even more sophisticated dynamical models describe the dynamics of *social power* under reflected appraisals (Jia et al. 2015; Ye et al. 2018), which is related to the French-DeGroot and the Friedkin-Johnsen model yet formally does not require to introduce opinions. It is assumed that social actors participate in infinitely many rounds of discussion, and, upon finishing each round, are able to find their social powers p_i (or, more generally, centralities c_i generated by the Friedkin-Johnsen model). The social power (an “appraisal” of an individual by the others) modifies the influence weights the individual assigns to the others in the next round, which, in turn, produces a new vector of social power (or Friedkin-Johnsen centralities).

Another important class of dynamical models describe the evolution of positive and negative ties leading to the structural balance. Whereas the balance is predicted by Heider’s theory, it does not provide any explicit description of the mechanisms balancing the network. Several mathematical models have been proposed in the literature (Marvel et al. 2011; Traag et al. 2013) to portray the dynamics of structural balance.

Dynamics and Control of Active Microcantilevers

Michael G. Ruppert¹ and S. O. Reza Moheimani²

¹The University of Newcastle, Callaghan, NSW, Australia

²The University of Texas at Dallas, Richardson, TX, USA

Abstract

The microcantilever is a key precision mechatronic component of many technologies for characterization and manipulation of matter at the nanoscale, particularly in the atomic force microscope. When a cantilever is operated in a regime that requires the direct excitation and measurement of its resonance frequencies, appropriate instrumentation and control is crucial for high-performance operation. In this entry, we discuss integrated cantilever actuation and present the cantilever transfer function model and its properties. As a result of using these active cantilevers, the ability to control the quality factor in order to manipulate the cantilever tracking bandwidth is demonstrated.

Introduction

The microcantilever is a precision mechatronic device and an integral component of a myriad of systems which have collectively enabled the steady progress in nanotechnology over the past three decades. It is a key component and sits at the heart of a variety of instruments for manipulation and interrogation at the nanoscale, such as atomic force microscopes, scanning probe lithography systems, high-resolution mass sensors, and probe-based data storage systems. Despite its apparent simplicity, the fast dynamics, particularly when interacting with nonlinear forces arising at the micro- and nanoscale, have motivated significant research on the design, identification, instrumentation, and control of these devices.

One of the most important applications of the microcantilever is in atomic force microscopy (AFM) Binnig et al. (1986). In dynamic AFM, the cantilever is actively driven at its fundamental resonance frequency while a sample is scanned underneath a sharp tip located at its extremity. As the tip interacts with the sample, changes occur in the oscillation amplitude, phase, and/or frequency which relate to surface features and material properties. By controlling the vertical interaction between the tip and the sample with a feedback controller, 3D images with atomic resolution can be obtained Giessibl (1995).

Examples of cantilevers used for AFM are shown in Fig. 1. The most conventional approach is to use a passive rectangular cantilever with an extremely sharp tip at the end etched from single-crystal silicon as shown in Fig. 1a. In order to oscillate the cantilever, a piezo-acoustic bulk actuator is typically used which is clamped to the chip body Bhushan (2010). While this approach is simple and effective, it leads to highly distorted frequency responses with numerous structural

modes of the mounting system appearing in the frequency response as can be seen in Fig. 1c. This renders the identification and subsequent analysis of the actual cantilever dynamics exceedingly difficult and model-based controller design nearly impossible.

In contrast, active cantilevers with integrated actuation and sensing on the chip level provide several distinct advantages over conventional cantilever instrumentation Rangelow et al. (2017). Most importantly, these include clean frequency responses, the possibility of down-scaling, parallelization to cantilever arrays, as well as the absence of optical interferences. While a number of integrated actuation methods have been developed over the years to replace the piezo-acoustic excitation, only electro-thermal and piezoelectric actuation can be directly integrated on the cantilever chip. An example of such a cantilever is shown in Fig. 1b which features an integrated piezoelectric transducer which can be used for actuation, deflection sensing, or both Ruppert and Moheimani (2013). As a consequence, this type of cantilever yields a clean frequency response, such as shown in Fig. 1d, for which frequency domain system identification yields very good models suitable for controller design.

Microcantilever Dynamics

Active microcantilevers allow the utilization of second-order transfer function models to accurately model their dynamics. Moreover, these models have favorable properties for robust vibration control which will be discussed in the following.

Cantilever Model

When a voltage is applied to the electrodes of the piezoelectric layer of a cantilever such as in Fig. 1b, the transfer function from actuator voltage $V(s)$ to cantilever deflection $D(s)$ of the first n flexural modes can be described by a sum of second-order modes Moheimani and Fleming (2006)

Dynamics and Control of Active Microcantilevers, Fig. 1 (a) Image of a commercially available passive AFM microcantilever (Asylum Research High Quality AFM probe, image courtesy of Oxford Instruments Asylum Research, Santa Barbara, CA) and sharp tip (User:MaterialsScientist, Wikimedia Commons, CC BY-SA 3.0). (b) Image of an AFM cantilever with

integrated piezoelectric transducer (Bruker, DMASP) for integrated actuation/sensing. (c) Frequency response measured with the AFM optical beam deflection sensor of a standard base-excited passive cantilever. (d) Frequency response and estimated transfer function model (1) of a cantilever with integrated piezoelectric actuation

$$G_{dv}(s) = \frac{D(s)}{V(s)} = \sum_{i=1}^n \frac{\alpha_i \omega_i^2}{s^2 + \frac{\omega_i}{Q_i} s + \omega_i^2} + d, \quad \alpha_i \in \mathbb{R} \quad (1)$$

where each term is associated with a specific vibrational mode shape (shown in the inset of Fig. 1d), quality (Q) factor Q_i , natural frequency ω_i , and gain α_i . The feedthrough term d takes into account the modeling error associated with limiting the sum to modes within the measurement bandwidth.

For the first eigenmode of the cantilever ($i = 1$), the poles of (1) are given by

$$p_{1,2} = -\frac{\omega_1}{2Q_1} \pm j\omega_1 \sqrt{1 - \frac{1}{4Q_1^2}}. \quad (2)$$

The real part of the eigenvalues characterizes the amplitude transient response time or cantilever tracking bandwidth as

$$f^c = \frac{f_1}{2Q_1}. \quad (3)$$

Example 1 For a standard tapping-mode microcantilever (e.g., Budget Sensors, TAP190-G) with a fundamental resonance frequency of $f_1 = 190$ kHz and a natural Q factor of 400, the tracking bandwidth is only approximately $f^c = 238$ Hz.

System Property

An important property of the cantilever transfer function for Q factor control (Q control) is its negative imaginary (NI) nature. In general, the transfer function G of a system is said to be NI if it is stable and satisfies the condition Petersen

and Lanzon (2010)

$$j[G(j\omega) - G^*(j\omega)] \geq 0 \quad \forall \omega > 0. \quad (4)$$

Moreover, G is strictly negative imaginary (SNI) if (4) holds with a strict inequality sign. It is straightforward to show that the first mode of $G_{dv}(s)$ is NI since $\alpha_1, \omega_1, Q_1 > 0$. If additionally, collocated actuators and sensors are available, this property can be extended to multiple modes of the cantilever Ruppert and Yong (2017). The benefit of this structural property results from the negative imaginary lemma which states that the positive feedback interconnection of an SNI plant and an NI controller is robustly stable if and only if the DC-gain condition $G(0)K(0) < 1$ is satisfied Lanzon and Petersen (2008). In other words, even in the case where the resonance frequency, modal gain, and/or damping of a cantilever mode change, as long as the NI property and DC-gain condition hold, the closed-loop system remains stable.

Microcantilever Control

In dynamic-mode AFM, the output of the vertical feedback (z-axis) controller resembles the surface topography only when the cantilever is oscillating in steady state. Therefore, a fast decaying transient response is highly desirable. Reduction of the cantilever Q factor using an additional feedback loop enables it to react faster to sample surface features. This, in turn, allows the gain of the regulating z-axis controller to be increased which improves the cantilever's ability to track the surface topography.

Q Control Using Positive Position Feedback

The positive position feedback (PPF) controller of the form

$$K_{PPF}(s) = \sum_{i=1}^m \frac{\gamma_{c,i}}{s^2 + 2\zeta_{c,i}\omega_{c,i}s + \omega_{c,i}^2}, \quad (5)$$

with $\gamma_{c,i}$, $\zeta_{c,i}$, and $\omega_{c,i}$ being the tunable controller parameters is an example of a model-based controller which can be used to control the Q factor of m modes of the cantilever. From its structure, it can be verified that it fulfills the negative imaginary property if $\gamma_{c,i}, \zeta_{c,i}, \omega_{c,i} > 0$, that is, robust stability is achieved if such a controller is used to dampen a negative imaginary mode of the cantilever.

The closed-loop system of the cantilever first mode ($n = 1$) in positive feedback with the PPF controller ($m = 1$) (5) can be written as

$$\ddot{z} + \underbrace{\begin{bmatrix} \frac{\omega_1}{Q_1} & 0 \\ 0 & 2\zeta_c\omega_c \end{bmatrix}}_{E=E^T} \dot{z} + \underbrace{\begin{bmatrix} \omega_1^2 & -\gamma_c\alpha_1\omega_1^2 \\ -\gamma_c\alpha_1\omega_1^2 & \omega_c^2 - \gamma_c d\gamma_c \end{bmatrix}}_{K=K^T} z = 0. \quad (6)$$

In order to show stability of the closed loop (6), E and K need to be positive definite. While $E > 0$ is given due to the NI property of plant and controller, for K to be positive definite, (6) can be rewritten into an LMI in the variables γ_c and ω_c^2 using the Schur complement as

$$\begin{bmatrix} \omega_1^2 & -\gamma_c\alpha_1\omega_1^2 & 0 \\ -\gamma_c\alpha_1\omega_1^2 & \omega_c^2 & \gamma_c \\ 0 & \gamma_c & d^{-1} \end{bmatrix} > 0. \quad (7)$$

Using the constraint (7), a feasible set of controller parameters can be calculated to initialize the controller design Boyd et al. (1994). This is demonstrated in the next subsection.

Controller Design

An effective approach to controller design is to perform a pole-placement optimization Ruppert and Moheimani (2016). This method places the real part of the closed-loop poles $\Re(p_{i,cl})$ at a desired location $p_{i,d} = \frac{\omega_1}{-2Q_1^*}$ by selecting a desired effective Q factor Q_1^* and finding a solution to the optimization problem

$$\begin{aligned} \min_{\gamma_c, \zeta_c, \omega_c} \quad & J(\gamma_c, \zeta_c, \omega_c) \\ \text{s.t.} \quad & \begin{bmatrix} \omega^2 & -\alpha\omega_1^2\gamma_c & 0 \\ -\gamma_c\alpha\omega_1^2 & \omega_c^2 & \gamma_c \\ 0 & \gamma_c & d^{-1} \end{bmatrix} > 0. \end{aligned} \quad (8)$$

Here, the cost function

$$\begin{aligned} J(\gamma_c, \zeta_c, \omega_c) = & \sum_{i=1}^4 (p_{i,d} - \Re(p_{i,cl}))^2 \\ & + \sum_{i=3}^4 |p_{i,cl} - p_{i-2,cl}|^2 \end{aligned} \quad (9)$$

penalizes the difference between the desired and actual pole locations and between poles that correspond to the same open-loop poles. Notice that the objective function is nonlinear in the optimization variables γ_c , ζ_c , and ω_c^2 , leading to a non-convex optimization problem. However in practice, initialization of the optimization problem with a feasible set calculated from (7) results in good convergence.

Example 2 Figure 2 demonstrates the effectiveness of this approach for reducing and increasing the Q factor of the first mode. In Fig. 2a, the Q factor was reduced from 268 to 10 by placing the closed-loop poles deeper into the left-half

plane, and in Fig. 2b the procedure shifts the closed-loop poles closer to the imaginary axis to yield a Q factor of 720. Increasing the Q factor may be desirable in applications where the cantilever is naturally heavily damped, for example, when the AFM cantilever is used for imaging in liquid.

Application to Atomic Force Microscopy

In order to demonstrate the improvement in cantilever tracking bandwidth, we report a high-speed tapping-mode AFM experiment in constant-height mode. In this mode, sample features entirely appear in the cantilever amplitude image and any imaging artifacts are due to insufficient cantilever bandwidth. Using the model-based Q controller presented in the previous section, the Q factor of the fundamental resonance of the piezoelectric cantilever is reduced to as low as $Q_1^* = 8$, resulting in a measured tracking bandwidth of 3.3 kHz, as shown in Fig. 3a, b. With the native Q factor of $Q = 222$, this is more than an order of magnitude faster than the native tracking bandwidth of approximately 100 Hz. When imaging an AFM calibration grating (NT-MDT TGZ3), the increase in bandwidth manifests itself

Dynamics and Control of Active Microcantilevers, Fig. 2 (a) Q factor reduction and (b) Q factor enhancement: Bode plot of the open-loop (—) and closed-loop

system (—) and pole-zero map of desired pole location (+), open-loop (x,o), and closed-loop (x,o) system

Dynamics and Control of Active Microcantilevers, Fig. 3 (a) Frequency response of the DMAPS cantilever in open loop (blue) and for various closed loops to reduce the Q factor (stated in the legend). (b) Tracking bandwidths of the DMAPS cantilever determined via drive

amplitude modulation for the frequency responses shown in (a) and color coded accordingly. (c) Resulting constant-height AFM images in open loop and for various closed loops, color coded accordingly

as better tracking of the rectangular surface features, as is visible in Fig. 3c. The controller was implemented on a Anadigm AN221E04 Field-Programmable Analog Array interfaced with a NT-MDT NTEGRA AFM which was operated at a scanning speed of 1 mm/s.

Summary and Future Directions

When a cantilever with integrated actuation is used for tapping-mode atomic force microscopy (AFM), the negative imaginary nature of its transfer function model allows robust resonant controllers to be used to regulate the quality (Q) factor of the fundamental resonance mode. This is of advantage, as it allows an increase in cantilever tracking bandwidth and therefore imaging speed. With the continuing development of AFM techniques, which make use of the excitation and detection of not only one but multiple eigenmodes of the cantilever, the ability to control these modes and their responses to excitation is believed to be the key to unraveling the true potential of these multifrequency AFM methods.

Economic Model Predictive Control

David Angeli

Department of Electrical and Electronic Engineering, Imperial College London, London, UK

Dipartimento di Ingegneria dell'Informazione, University of Florence, Florence, Italy

Abstract

Economic model predictive control (EMPC) is a variant of model predictive control aimed at maximization of system's profitability. It allows one to explicitly deal with hard and average constraints on system's input and output variables as well as with nonlinearity of dynamics. We provide basic definitions and concepts of the approach and highlight some promising research directions.

Keywords

Constrained systems · Dynamic programming · Profit maximization

Introduction

Most control tasks involve some kind of economic optimization. In classical linear quadratic (LQ) control, for example, this is cast

as a trade-off between control effort and tracking performance. The designer is allowed to settle such a trade-off by suitably tuning weighting parameters of an otherwise automatic design procedure.

When the primary goal of a control system is profitability rather than tracking performance, a suboptimal approach has often been devised, namely, a hierarchical separation is enforced between the economic optimization layer and the dynamic real-time control layer.

In practice, while set points are computed by optimizing economic revenue among all equilibria fulfilling the prescribed constraints, the task of the real-time control layer is simply to drive (basically as fast as possible) the system's state to the desired set-point value.

Optimal control or LQ control may be used to achieve the latter task, possibly in conjunction with model predictive control (MPC), but the actual economics of the plant are normally neglected at this stage.

The main benefits of this approach are twofold:

1. Reduced computational complexity with respect to infinite-horizon dynamical programming
2. Stability robustness in the face of uncertainty, normally achieved by using some form of robust control in the real-time control layer

The hierarchical approach, however, is suboptimal in two respects:

1. First of all, given nonlinearity of the plant's dynamics and/or nonconvexity of the functions characterizing the economic revenue, there is no reason why the most profitable regime should be an equilibrium.
2. Even when systems are most profitably operated at equilibrium, transient costs are totally disregarded by the hierarchical approach, and this may be undesirable if the time constants of the plant are close enough to the time scales at which set point's variations occur.

Economic model predictive control seeks to remove these limitations by directly using the economic revenue in the stage cost and by the formulation of an associated dynamic optimization problem to be solved online in a receding horizon manner. It was originally developed by Rawlings and co-workers, in the context of linear control systems subject to convex constraints as an effective technique to deal with infeasible set points (Rawlings et al. 2008) (in contrast to the classical approach of redesigning a suitable quadratic cost that achieves its minimum at the closest feasible equilibrium). Preserving the original cost has the advantage of slowing down convergence to such an equilibrium when the transient evolution occurs in a region where the stage cost is better than at steady state. Stability and convergence issues are at first analyzed, thanks to convexity and for the special case of linear systems only. Subsequently Diehl introduced the notion of rotated cost (see Diehl et al. 2011) that allowed a Lyapunov interpretation of stability criteria and paved the way for the extension to general dissipative nonlinear systems (Angeli et al. 2012).

Economic MPC Formulation

In order to describe the most common versions of economic MPC, assume that a discrete-time finite-dimensional model of state evolution is available for the system to be controlled:

$$x^+ = f(x, u) \quad (1)$$

where $x \in X \subset \mathbb{R}^n$ is the state variable, $u \in U \subset \mathbb{R}^m$ is the control input, and $f: X \times U \rightarrow X$ is a continuous map which computes the next state value, given the current one and the value of the input. We also assume that $\mathbb{Z} \subset X \times U$ is a compact set which defines the (possibly coupled) state/input constraints that need to hold pointwise in time:

$$(x(t), u(t)) \in \mathbb{Z} \quad \forall t \in \mathbb{N}. \quad (2)$$

In order to introduce a measure of economic performance, to each feasible state/input pair $(x, u) \in \mathbb{Z}$, we associate the instantaneous net cost of operating the plant at that state when feeding the specified control input:

$$\ell(x, u) : \mathbb{Z} \rightarrow \mathbb{R}. \quad (3)$$

The function ℓ (which we assume to be continuous) is normally referred to as stage cost and together with actuation and/or inflow costs should also take into account the profits associated to possible output/outflows of the system. Let (x^*, u^*) denote the best equilibrium/control input pair associated to (3) and (2), namely,

$$\begin{aligned} \ell(x^*, u^*) &= \min_{x, u} \ell(x, u) \\ &\text{subject to} \\ &(x, u) \in \mathbb{Z} \\ &x = f(x, u) \end{aligned} \quad (4)$$

Notice that, unlike in tracking MPC, it is not assumed here that

$$\ell(x^*, u^*) \leq \ell(x, u) \quad \forall (x, u) \in \mathbb{Z}. \quad (5)$$

This is, technically speaking, the main point of departure between economic MPC and tracking MPC.

As there is no natural termination time to operation of a system, our goal would be to optimize the infinite-horizon cost functional:

$$\sum_{t \in \mathbb{N}} \ell(x(t), u(t)) \quad (6)$$

possibly in an average sense (or by introducing some discounting factor to avoid infinite costs) and subject to the dynamic/operational constraints (1) and (2).

To make the problem computationally more tractable and yet retain some of the desirable economic benefits of dynamic programming, (6) is truncated to the following cost functional:

$$J(\mathbf{z}, \mathbf{v}) = \sum_{k=0}^{N-1} \ell(z(k), v(k)) + V_f(z(N)) \quad (7)$$

where $\mathbf{z} = [z(0), z(1), \dots, z(N)] \in X^{N+1}$, $\mathbf{v} = [v(0), v(1), \dots, v(N-1)] \in U^N$ and $V_f : X \rightarrow \mathbb{R}$ is a terminal weighting function whose properties will be specified later.

The virtual state/control pair $(\mathbf{z}^*, \mathbf{v}^*)$ at time t is the solution (which for the sake of simplicity we assume to be unique) of the following optimization problem:

$$\begin{aligned} & V(x(t)) = \min_{\mathbf{z}, \mathbf{v}} J(\mathbf{z}, \mathbf{v}) \\ & \text{subject to} \\ & z(k+1) = f(z(k), v(k)) \\ & (z(k), v(k)) \in \mathbb{Z} \\ & \text{for } k \in \{0, 1, \dots, N-1\} \\ & z(0) = x(t), z(N) \in \mathbb{X}_f. \end{aligned} \quad (8)$$

Notice that $z(0)$ is initialized at the value of the current state $x(t)$. Thanks to this fact, $\mathbf{z}^*$ and $\mathbf{v}^*$ may be seen as functions of the current state $x(t)$. At the same time, $z(N)$ is constrained to belong to the compact set $\mathbb{X}_f \subset X$ whose properties will be detailed in the next paragraph.

As customary in model predictive control, a state-feedback law is defined by applying the first virtual control to the plant, that is, by letting $u(t) = v^*(0)$ and restating, at the subsequent time instant, the same optimization problem from initial state $x(t+1)$ which, in the case of exact match between plant and model, can be computed as $f(x(t), u(t))$.

In the next paragraph, we provide details on how to design the “terminal ingredients” (namely, V_f and $\mathbb{X}_f$) in order to endow the basic algorithm (8) with important features such as recursive feasibility and a certain degree of average performance and/or stability.

Hereby it is worth pointing out how, in the context of economic MPC, it makes sense to treat, together with pointwise-in-time constraints, asymptotic average constraints on specified input/output variables. In tracking applications, where the control algorithm guarantees asymptotic convergence of the state to a feasible set point, the average asymptotic value of all input/output variables necessarily matches that of the corresponding equilibrium/control input pair. In economic MPC, the asymptotic regime resulting in closed loop may, in general, fail to be an equilibrium; therefore, it might be of interest to impose average constraints on system’s inflows and outflows which are more stringent than those indirectly implied by the fulfillment of (2). To this end, let the system’s output be defined as

$$y(t) = h(x(t), u(t)) \quad (9)$$

with $h(x, u) : \mathbb{Z} \rightarrow \mathbb{R}^p$, a continuous map, and consider the convex compact set $\mathbb{Y}$. We may define the set of asymptotic averages of a bounded signal y as follows:

$$\begin{aligned} \text{Av}[y] &= \left\{ \eta \in \mathbb{R}^p : \exists \{t_n\}_{n=1}^{\infty} : t_n \rightarrow \infty \text{ as } n \rightarrow \infty \right. \\ &\quad \left. \text{and } \eta = \lim_{n \rightarrow \infty} \left(\frac{\sum_{k=0}^{t_n-1} y(k)}{t_n} \right) \right\} \end{aligned}$$

Notice that for converging signals, or even for periodic ones, $\text{Av}[y]$ always is a singleton but may fail to be such for certain oscillatory regimes. An asymptotic average constraint can be expressed as follows:

$$\text{Av}[y] \subseteq \mathbb{Y} \quad (10)$$

where y is the output signal as defined in (9).

Basic Theory

The main theoretical results in support of the approach discussed in the previous paragraph are discussed below. Three fundamental aspects are treated:

- Recursive feasibility and constraint satisfaction
- Asymptotic performance
- Stability and convergence

Feasibility and Constraints

The departing point of most model predictive control techniques is to ensure recursive feasibility, namely, the fact that feasibility of the problem (8) at time 0 implies feasibility at all subsequent times, provided there is no mismatch between the true plant and its model (1). This is normally achieved by making use of a suitable notion of control invariant set which is used as a terminal constraint in (8). Economic model predictive control is not different in this respect, and either one of the following set of assumptions is sufficient to ensure recursive feasibility:

1. Assumption 1: Terminal constraint

$$\mathbb{X}_f = \{x^*\} \quad V_f = 0$$

2. Assumption 2: Terminal penalty function

There exists a continuous map $\kappa : \mathbb{X}_f \rightarrow U$ such that

$$\begin{aligned} (x, \mathbb{K}(x)) &\in \mathbb{Z} & \forall x \in \mathbb{X}_f \\ f(x, \mathbb{K}(x)) &\in \mathbb{X}_f & \forall x \in \mathbb{X}_f \end{aligned}$$

The following holds:

Theorem 1 *Let $x(0)$ be a feasible state for (8), and assume that either Assumption 1 or 2 holds. Then, the closed-loop trajectory $x(t)$ resulting from receding horizon implementation of the feedback $u(t) = v^*(0)$ is well defined for all $t \in \mathbb{N}$ (i.e., $x(t)$ is a feasible initial state of (8) for all $t \in \mathbb{N}$), and the resulting closed-loop variables $(x(t), u(t))$ fulfill the constraints in (2).*

The proof of this Theorem can be found in Angeli et al. (2012) and Amrit et al. (2011), for instance. When constraints on asymptotic averages are of interest, the optimization problem (8) can be augmented by the following constraints:

$$\sum_{k=0}^{N-1} h(z(k), v(k)) \in \mathbb{Y}_t \quad (11)$$

provided $\mathbb{Y}_t$ is recursively defined as

$$\mathbb{Y}_{t+1} = \mathbb{Y}_t \oplus \mathbb{Y} \oplus \{-h(x(t), u(t))\} \quad (12)$$

where $\oplus$ denotes Pontryagin's set sum. ($A \oplus B := \{c : \exists a \in A, \exists b \in B : c = a + b\}$) The sequence is initialized as $\mathbb{Y}_0 = N\mathbb{Y} \oplus \mathbb{Y}_{00}$ where $\mathbb{Y}_{00}$ is an arbitrary compact set in $\mathbb{R}^p$ containing 0 in its interior. The following result can be proved.

Theorem 2 *Consider the optimization problem (8) with additional constraints (11), and assume that $x(0)$ is a feasible initial state. Then, provided a terminal equality constraint is adopted, the closed-loop solution $x(t)$ is well defined and feasible for all $t \in \mathbb{N}$, and the resulting closed-loop variable $y(t) = h(x(t), u(t))$ fulfills the constraint (10).*

Extending average constraints to the case of economic MPC with terminal penalty function is possible but outside the scope of this brief tutorial. It is worth mentioning that the set $\mathbb{Y}_{00}$ plays the role of an initial allowance that is shrunk or expanded as a result of how close are closed-loop output signals to the prescribed region. In particular, $\mathbb{Y}_{00}$ can be selected a posteriori (after computation of the optimal trajectory) just for $t = 0$, so that the feasibility region of the algorithm is not affected by the introduction of average asymptotic constraints.

Asymptotic Average Performance

Since economic MPC does not necessarily lead to converging solutions, it is important to have bounds which estimate the asymptotic average performance of the closed-loop plant. To this end, the following dissipation inequality is needed for the approach with terminal penalty function:

$$V_f(f(x, \mathbb{K}(x))) \leq V_f(x) - \ell(x, \mathbb{K}(x)) + \ell(x^*, u^*) \quad (13)$$

which shall hold for all $x \in \mathbb{X}_f$. We are now ready to state the main bound on the asymptotic performance:

Theorem 3 Let $x(0)$ be a feasible state for (8), and assume that either Assumption 1 or Assumption 2 together with (13) holds. Then, the closed-loop trajectory $x(t)$ resulting from receding horizon implementation of the feedback $u(t) = v^*(0)$ is well defined for all $t \in \mathbb{N}$ and fulfills

$$\limsup_{T \rightarrow +\infty} \frac{\sum_{t=0}^{T-1} \ell(x(t), u(t))}{T} \leq \ell(x^*, u^*). \quad (14)$$

The proof of this fact can be found in Angeli et al. (2012) and Amrit et al. (2011). When periodic solutions are known to outperform, in an average sense, the best equilibrium/control pair, one may replace terminal equality constraints by periodic terminal constraints (see Angeli et al. 2012). This leads to an asymptotic performance at least as good as that of the solution adopted as a terminal constraint. See Angeli et al. (2016) for extensions to the case of time-varying costs.

Stability and Convergence

It is well known that the cost-to-go $V(x)$ as defined in (8) is a natural candidate Lyapunov function for the case of tracking MPC. In fact, the following estimate holds along solutions of the closed-loop system:

$$V(x(t+1)) \leq V(x(t)) - \ell(x(t), u(t)) + \ell(x^*, u^*). \quad (15)$$

This shows, thanks to inequality (5), that $V(x(t))$ is nonincreasing. Owing to this, stability and convergence can be easily achieved under mild additional technical assumptions. While property (15) holds for economic MPC, both in the case of terminal equality constraint and terminal penalty function, it is no longer true that (5) holds. As a matter of fact, x^* might even fail to be an equilibrium of the closed-loop system, and hence, convergence and stability cannot be expected in general.

Intuitively, however, when the most profitable operating regime is an equilibrium, the average performance bound provided by Theorem 3 seems to indicate that some form of stability or convergence to x^* could be expected. This is

true under an additional dissipativity assumption which is closely related to the property of optimal operation at steady state.

Definition 1 A system is strictly dissipative with respect to the supply function $s(x, u)$ if there exists a continuous function $\lambda : X \rightarrow \mathbb{R}$ and $\rho : X \rightarrow \mathbb{R}$ positive definite with respect to x^* such that for all x and u in $X \times U$, it holds:

$$\lambda(f(x, u)) \leq \lambda(x) + s(x, u) - \rho(x). \quad (16)$$

The next result highlights the connection between dissipativity of the open-loop system and stability of closed-loop economic MPC.

Theorem 4 Assume that either Assumption 1 or Assumption 2 together with (13) holds. Let the system (1) be strictly dissipative with respect to the supply function $s(x, u) = \ell(x, u) - \ell(x^*, u^*)$ as from Definition 1 and assume there exists a neighborhood of feasible initial states containing x^* in its interior. Then provided V is continuous at x^* , x^* is an asymptotically stable equilibrium with basin of attraction equal to the set of feasible initial states.

See Angeli et al. (2012) and Amrit et al. (2011) for proofs and discussions. Convergence results are also possible for the case of economic MPC subject to average constraints. Details can be found in Müller et al. (2014).

Hereby it is worth mentioning that finding a function satisfying (16) (should one exist) is in general a hard task (especially for nonlinear systems and/or nonconvex stage costs); it is akin to the problem of finding a Lyapunov function, and therefore general construction methods do not exist. Let us emphasize, however, that while existence of a storage function λ is a sufficient condition to ensure convergence of closed-loop economic MPC, formulation and resolution of the optimization problem (8) can be performed irrespectively of any explicit knowledge of such function. Also, we point out that existence of λ as in Definition 1 and Theorem 4 is only possible if the optimal infinite-horizon regime of operation for the system is an equilibrium.

Summary and Future Directions

Economic model predictive control is a fairly recent and active area of research with great potential in those engineering applications where economic profitability is crucial rather than tracking performance.

The technical literature is rapidly growing in application areas such as chemical engineering (see Heidarinejad 2012) or power systems engineering (see Hovgaard et al. 2010; Müller et al. 2014) where system's output is in fact physical outflows which can be stored with relative ease.

We only dealt with the basic theoretical developments and would like to provide pointers to interesting recent and forthcoming developments in this field:

- Generalized terminal constraints: possibility of enlarging the set of feasible initial states by using arbitrary equilibria as terminal constraints, possibly to be updated on line in order to improve asymptotic performance (see Fagiano and Teel 2012; Müller et al. 2013).
- Economic MPC without terminal constraints: removing the need for terminal constraints by taking a sufficiently long control horizon is an interesting possibility offered by standard tracking MPC. This is also possible for economic MPC at least under suitable technical assumptions as investigated in Grüne (2012, 2013). Another related line of investigation has recently focused on the link between Turnpike Properties and design of closed-loop Economic MPC algorithms (Faulwasser and Bonvin 2015)
- Generalized optimal regimes of operation (beyond steady state) are considered in Dong and Angeli (2018a)
- The basic developments presented in the previous paragraph only deal with systems unaffected by uncertainty. This is a severe limitation of initial approaches and, as for the case of tracking MPC, a great deal of research in this area is currently being developed, see Bayer et al. (2014) and Dong and Angeli (2018b). In particular, both deterministic and stochastic uncertainties are of interest, and tube-based or scenario based solutions.

Electric Energy Transfer and Control via Power Electronics

Fred Wang

University of Tennessee, Knoxville, TN, USA

Abstract

Power electronics and their applications for electric energy transfer and control are introduced. The fundamentals of the power electronics are presented, including the commonly used semiconductor devices and power converter circuits. Different types of power electronics controllers for electric power generation, transmission and distribution, and consumption are described. The advantages of power electronics over

traditional electromechanical or electromagnetic controllers are explained. The future directions for power electronics application in electric power systems are discussed.

Keywords

Power electronics · Electric energy transfer · Electric energy control

Introduction

Modern society runs on electricity or electric energy. The electric energy generally must be transferred before consumption since the energy sources, such as thermal power plants, hydro dams, and wind farms, are often some distances away from the loads. In addition, electric energy needs to be controlled as well since the energy transfer and use often require electricity in a form different from the raw form generated at the source. Examples are the voltage magnitude and frequency. For long-distance transmission, the voltage needs to be stepped up at the sending end to reduce the energy loss along the lines and then stepped down at the receiving end for users; for many modern consumer devices, DC voltage is needed and obtained through transforming the 50 or 60 Hz utility power. Note that electric energy transfer and control is often used interchangeably with the electric power transfer and control. This is because the modern electric power systems have very limited energy storage, and the energy generated must be consumed at the same time. Even with its growing use, the energy storage is mainly connected to the system to either act as load or source, and its power transfer is part of the system power transfer.

Since the beginning of the electricity era, electric energy transfer and control technologies have been an essential part of electric power systems. Many types of equipment were invented and applied for these purposes. The commonly used equipment includes electric transmission and distribution lines, generators, transformers, switchgears, inductors or reactors, and capacitor banks. The traditional equipment has limited

control capability. Many cannot be controlled at all or can only be connected or disconnected with mechanical switches, others with limited range, such as transformers with tap changers. Even with fully controllable equipment such as generators, the control dynamics is relatively slow due to the electromechanical or electro magnetic nature of the controller.

Power electronics are based on semiconductor devices. These devices are derivatives from transistors and diodes used in microelectronic circuits with the additional large power handling capability. Due to their electronic nature, power electronic devices are much more flexible and faster than their electromechanical or electromagnetic counterparts for electric energy transfer and control. Since the advent of power electronics in the 1950s, they have steadily gained ground in power systems applications. Today, power electronics controllers are an important part of equipment for electric energy transfer and control. Their roles are growing rapidly with the continuous improvement of the power electronics technologies.

Fundamentals of Power Electronics

Different from semiconductor devices in microelectronics, the power electronic devices only act as switches for desired control functions, such that they incur minimum losses when they are either on (closed) or off (open). As a result, the power electronics controllers are basically switching circuits. The semiconductor switches are therefore the most important elements of the power electronics controllers. Since the 1950s, many different types of power semiconductor switches have been developed and can be selected based on the applications.

The performance of the power semiconductor devices is mainly characterized by their voltage and current ratings, conduction or on-state loss, as well as the switching speed (or switching frequency capability) and associated switching loss. Main types of power semiconductor devices are listed with their symbols and state-of-the-

Electric Energy Transfer and Control via Power Electronics, Table 1 Commonly use Si-based power semiconductor devices and their ratings

Types	Symbol	Voltage	Current	Switching frequency
Power diodes		Max 80 kV, typical <10 kV	10 kA	Various
Thyristor		Max 8 kV	4.5 kA	AC line frequency
GTO		Max 10 kV	6.5 kA	<500 Hz
Power MOSFET		Max 4.5 kV, typical <600 V	1.6 kA	10s of kHz to MHz
IGBT		Max 6.5 kV, typical >600 V	2.4 kA	1 kHz to 10s of kHz
IGCT		Max 10 kV, typical >4.5 kV	6.5 kA	<2 kHz

E

art rating and frequency range shown in Table 1 (Rahimo and Klaka 2009).

- Power diode – a two-terminal device with similar characteristics to diodes used in microelectronics but with higher voltage and power ratings.
- Thyristor – also called SCR (silicon-controlled rectifier). Unlike diode, thyristor is a three-terminal device with an additional gate terminal. It can be turned on by a current pulse through gate but can only be turned off when the main current goes to zero with external means. Thyristor has low conduction loss but slow switching speed.
- GTO – stands for gate-turn-off thyristor. GTO can be turned on similarly as a regular thyristor and can also be turned off with a large negative gate current pulse. GTO has been largely replaced by IGBT and IGCT due to its complex gate driving needs and slow switching speed.
- Power BJT – similar to bipolar transistor for microelectronics and requires a sustained gate current to turn on and off. It has been replaced by IGBT and power MOSFET with simpler gate signals and faster switching speed.
- Power MOSFET – similar to metal-oxide semiconductor field effect transistor for microelectronics and can be turned on and off with a gate voltage signal. It is the fastest device available but has relatively

high conduction loss and relatively low voltage/power ratings.

- IGBT – stands for insulated-gate bipolar transistor. Unlike regular BJT, it can be turned on and off with a gate voltage like MOSFET. It has relatively low conduction loss and fast switching speed. IGBT is becoming the workhorse of the power electronics for high-power applications.
- IGCT – stands for integrated gate-commutated thyristor. It is basically a GTO with an integrated gate drive circuit allowing a hard-driven turnoff. It therefore has faster switching speed than regular GTO but slower than IGBT.

Except for diodes, all other devices above can be turned on and/or off through a gate signal, so they are active switches, while diodes are called passive switch.

Note that devices in Table 1 are all based on Si. Since 1950s, Si power semiconductor devices have gone through many generations of development and are approaching material theoretical limitations in terms of blocking voltage, operation temperature, and conduction and switching characteristics. In recent years, semiconductor devices based on wide bandgap (WBG) (energy bandgap significantly higher than 1 eV) materials have progressed rapidly that promises to revolutionize next-generation power electronics converters. Compared with the Si (energy bandgap around 1 eV) devices,

WBG devices feature high breakdown electric field, low specific on-resistance, fast switching speed, and high junction temperature capability. These characteristics are beneficial for efficiency, high power and voltage capability, size, and cost of power electronics converters, which are all important for power electronics applications as energy transfer controllers in power systems.

The WBG devices under rapid development and commercialization include silicon carbide (SiC) and gallium nitride (GaN) devices, with SiC mainly targeting high-voltage high-power (600 V, kilowatts or above) applications and GaN for low-voltage low-power (600 V, kilowatts or below) applications (Millan et al. 2014; Wang et al. 2015; Wang and Zhang 2016).

Similar to Si semiconductors, WBG semiconductors can be used to realize various power devices. The more mature SiC-based devices already include diodes (both Schottky diodes and PIN diodes), MOSFETs, IGBTs, and thyristors with the voltage range from 400 V to 22.6 kV. In some cases, SiC junction gate FETs (JFETs) and bipolar junction transistors (BJTs) are also available and used. The low-voltage (from 400 to 1700 V) SiC devices are already commercially available. Among them, the current rating per die approaches 100 A, and with multiple dies in parallel, state-of-the-art SiC power modules on market can deliver hundreds of amperes of current. The high-voltage SiC devices (3.3 kV and above) are generally still in development stages and with small current rating per die; however, their further development and commercialization

are expected in the near future and will help to improve electric energy transfer controllers.

With different types of power semiconductors, many power electronics circuits have been developed. Based on their functions, they can be classified as:

- Rectifier – rectifiers convert AC to DC. Depending on AC sources, rectifiers can be three-phase or single-phase; depending on device types, they can be passive (diode-based), phase-controlled (thyristor-controlled), or actively switched.
- Inverter – inverters convert DC to AC. They again can be three-phase or single-phase. Inverters generally require active switching devices.
- DC-DC converter – also called chopper, DC-DC converter converts one DC voltage level to another. Sometimes it also contains a magnetic isolation. DC-DC converter can have unidirectional or bidirectional power flow and generally requires active switching devices.
- AC-AC converter – directly converts one AC to another, either only the voltage magnitude or both magnitude and frequency. The former can also be called AC switch, and the latter can be called frequency changer. Active devices are needed for these types of converters.

There are a variety of converter topologies for each type of the converters listed above. The most commonly used basic topologies for power system applications are shown in Fig. 1.

Electric Energy Transfer and Control via Power Electronics, Fig. 1 Commonly used basic power electronics converter topologies (only one phase shown for the AC

switch). (a) Thyristor-based rectifier. (b) Voltage source inverter (VSI). (c) Bidirectional AC switch

These basic topologies can be expanded through paralleling or series of devices and/or converters to achieve higher current and voltage ratings. Other variations such as multilevel converters are also popular for high-voltage applications using lower-voltage rating devices.

It should be noted that passive components, i.e., inductors and capacitors, are essential parts of power electronics converters. In fact, power electronics converters transfer or control the electric energy by storing it temporarily in inductors or capacitors while reformat the original voltage or current waveform through switching actions. The other key function of the passives is filtering the harmonics caused by switching.

Power Electronics Controller Types for Energy Transfer and Control

For almost all traditional non-power electronics equipment for electric energy transfer and control, there can be corresponding power electronics-based counterpart, often with better controllability. However, power electronics equipment can be more expensive and therefore only used when it provides better overall performance and cost benefits. In other cases, only power electronics equipment can achieve the required control functions.

The power electronics controllers can be categorized as for energy generation, delivery, and consumption. For generation, the thermal or hydro generators both use synchronous machines with excitation windings on the rotor, which require DC current. A thyristor-based rectifier, called exciter, is generally used for this purpose. Wind turbine generators usually use a back-to-back VSI to interface to the AC grid, and PV solar sources use a DC-DC converter cascaded with a VSI.

Power electronics controllers for transmission and distribution controllers include the so-called flexible AC transmission systems (FACTS) and high-voltage DC transmission (HVDC) (Hingorani and Gyugyi 2000). Some of the more commonly used controllers and their functions and circuit topologies are listed in Table 2 (Wang et al. 2003).

The main power electronics controllers for loads include variable speed motor drives, electronic ballast for florescent lights and power supplies for LED, various power supplies for computer, IT and other electronic loads, and chargers for electric vehicles. The percentage of power electronics controlled loads in power systems has been steadily increasing. Power electronics can generally result in improved performance and efficiency.

Future Directions

Power electronics have progressed steadily since the invention of thyristors in the 1950s. The progress is in all aspects, semiconductor devices, passives, circuits, control, and system integration, leading to converter systems with better performance, higher efficiency, higher power density, higher reliability, and lower cost. Because of these progresses, the power electronics applications in power systems have become more and more widespread. However, in general, power electronics controllers are still not sufficiently cost-effective, reliable, or efficient. Many improvements are needed and expected, especially in the following areas:

- Semiconductor devices – Devices used today are almost exclusively based on silicon. The emerging devices based on wide bandgap materials such as SiC and GaN are expected to revolutionize power electronics with their capabilities of higher voltage, lower loss, faster switching speed, higher temperature, and smaller size.
- Power electronics converters – More cost-effective and reliable converters will be developed as a result of better devices, passive components, and circuit structures. Modular, distributed, and hybrid with non-power electronics approaches are expected to result in overall better benefits.
- Enhanced functions – Power electronics controllers can be designed to have multiple functions in the system. For example, wind and PV solar inverters can provide reactive power to the grid in addition

Electric Energy Transfer and Control via Power Electronics, Table 2 Commonly used power electronics controllers for transmission and distribution

Controller	One-line configuration	System functions	Control principle	Basic PE function
SVC – Static Var Compensator with Thyristor-Controlled Reactor and Capacitor		Stability enhancement Voltage regulation & VAR compensation	VAR control through varying L & C in shunt connection	Controlled bi-directional AC switch
TCSC – Thyristor-Controlled Series Capacitor		Power flow control Stability enhancement Fault current limiting	Power & VAR control through varying C & L in series connection	Controlled bi-directional AC switch
SSTS – Solid State Transfer Switch		Power supply transfer for reliability and power quality	On and off control	Controlled bi-directional AC switch
HVDC (Classic)		System interconnection Power flow control Stability enhancement	Power control through back-to-back converters in shunt connections	Bi-directional AC/DC current source converter
SSSC – Static Series Synchronous compensator		Power flow control Stability enhancement	VAR control through voltage control in series connection	Bi-directional AC/DC voltage source converter
STATCOM – Static Synchronous Compensator		Stability enhancement Voltage regulation & VAR compensation	VAR control through current control in shunt connection	Bi-directional AC/DC voltage source converter
HVDC (Voltage Source)		System interconnection Power flow control Stability enhancement	Power and Var control through back-to-back converters in shunt connections	Bi-directional AC/DC voltage source converter

to transferring real energy. Today, power electronics controllers are mostly locally controlled. With better measurement and communication technologies, they may be controlled over a wide area for supporting the system-level functions. With more system-level functions, power electronics converters also need to be designed to consider grid operating conditions.

- New applications – The new applications for future power system include DC grid based on multiterminal HVDC and energy storage. Critical technologies include cost-effective

and efficient DC transformers and DC circuit breakers. Power electronics will play key roles in these technologies. The emerging WBG device technologies will help enable these new applications.

Emergency Building Control

Veronica A. Adetola
Pacific Northwest National Laboratory,
Richland, WA, USA

Abstract

The number and frequency of emergency events in buildings are increasing. Rapid situational awareness and effective control require greater integration and coordination between diverse building systems. This entry

provides an overview of emergency events and response in buildings and highlights some future research directions.

Keywords

Emergency response · Hazardous contaminants · Cyber security · Power outage · Mitigation · Building management system (BMS)

E

Introduction

There is no universally accepted definition or classification of an emergency situation. For this entry, building emergency is defined as an event or circumstance that can cause death or significant injuries to the building occupants, cause physical damage, or significantly disrupt the building operations. Such events include fire outbreak, hazardous agent release, active shooter incidents, power outages, cyber-attacks, and severe weather. The building sector has made significant strides in deploying safety and response systems for traditional events such as fire. While these systems are heavily regulated, response strategies for the newer and increasing threats such as active shooters, biological/chemical threats, and cyber-attacks are still at a nascent stage with significant gaps and opportunities. An effective response requires a multilayer strategy to allow for threat assessment and to assure the highest possible levels of security and safety.

Figure 1 shows an exemplary multi-tiered response strategy for building emergencies. The decision options depend on the available information and may have a range of impacts on the building and its occupants, from low and localized impact (e.g., redirecting airflows in the case of hazardous agent release) to high impact (e.g., building shutdown and remediation). The automated low-impact response provides immediate action, upon the detection of a threat or occurrence of an emergency event, and mitigates impact. The low-impact response is usually followed by additional data collection and threat confirmation. If the threat is

Emergency Building Control, Fig. 1 Tiered response reduces impact while threat is assessed. Adapted from (Wagner et al. 2018)

verified, a high-impact response is implemented. The following sections discuss some of the emergency events in buildings and automated low-impact response strategies.

Physical Attack: Hazardous Agents

The number of hazardous (i.e., chemical or biological) agent attacks in indoor environments is growing. Examples include the 2001 anthrax attacks in the United States and the recent nerve agent attacks in Malaysia and Salisbury, England. Typical commercial buildings have no system to actively mitigate these threats; they rely primarily on restricted access for security and onsite video cameras for post-event forensics (Wagner et al. 2018). Commercially available sensors exist for monitoring chemical and biological threats (e.g., *TACBIO 2*, *FLIR IBAC 2*, *Polaron F10*), and there are ongoing efforts such as the Department of Homeland Security's (DHS) SenseNet program to develop reliable low-cost sensors for real-time detection of biological threats in indoor environments. (<https://www.dhs.gov/science-and-technology/detection-and-diagnostics>) The advancements in smart connected buildings, along with these sensor technologies, can be leveraged to

provide an automated initial response to the release of a hazardous agent and mitigate impact prior to the arrival of first responders.

Recent work has demonstrated the potential of using building infrastructure for effective low-impact response (Wagner et al. 2018). The study, based on a validated CONTAM (*CONTAM* is a software tool developed by NIST for modeling multi-zone airflow and contaminant transport in buildings.) model of an office building, shows that increasing the HVAC ventilation to the affected area resulted in a 70% reduction in the contaminant spread to the adjacent rooms (measured 30 min after release). The most effective response depends on the hazardous agent type (chemical or biological), source location (indoor or outdoor), and concentration. Different automated building HVAC control actions can be enacted following a detection to minimize exposure to such agents during the initial release. This may include increasing air exchange rates between outdoor and affected indoor space, shutting down the HVAC system that serves the affected zones to confine the contaminant, and pressurizing the unaffected zones with outdoor air. For a building that is equipped with a chemical or biological filtration system, an immediate response to an outdoor release

will be to over-pressurize the building with the treated air, thereby preventing contaminated outdoor air from entering the building. While these responses will help slow the spread of contaminants in the building, the occupants must be monitored for thermal comfort and O₂ deprivation, and the response strategy must preserve the reliability of the HVAC equipment (e.g., limit air intake during subfreezing weather conditions). Selecting the best response for a given scenario calls for an advanced control strategy that effectively coordinates the use of building HVAC controls and other assets (e.g., access control) while respecting the building's safe operational constraints.

Cyber-Attack

As buildings are becoming more intelligent and (Internet) connected, their resiliency to cyber-attacks becomes vital. The current generation of Building Management Systems (BMS) are designed for functionality with little attention to their software and physical components security. The vulnerabilities in BMS can be exploited to create an emergency situation. An attacker can remotely turn off ventilation to a chemical room, allowing harmful fumes to spread in a building or turn off the lighting or ventilation system at the most inconvenient time to destabilize the occupants or cause an unplanned evacuation. The emerging grid-interactive technologies increase the building system's exposure, providing newer entry points for hackers to disrupt both the building and grid operations. Examples include an attacker who alters demand reduction event data (level or price) to mislead customers, resulting in sudden disruption of utility operations. Experts have asserted that a large-scale coordinated and simultaneous attack on grid-edge devices (including buildings) could have severe implications for reliable power grid services. The recent vulnerability assessments (<https://securityledger.com/2016/02/ibm-research-calls-out-smart-building-risks/>) and cyber security incidents (<https://ics-cert.us-cert.gov/>) have spurred

cyber-aware campaigns and development of advanced cyber intrusion and response methods.

There are ongoing efforts to protect industrial control systems including BMS from cyber-attacks. The popular information technology-based security designs (such as antivirus and patching policy, encryption, cryptographic mechanisms) can only provide assurance that cyber-attacks will be less likely to succeed but do not provide immunity against new and unknown attacks. Adverse cyber events must be treated as both security and resiliency issues. (*NIST Special Publication 800–160 Vol. 2 (DRAFT)*.) To achieve attack resiliency, the BMS needs to be continuously monitored for complete situational awareness and targeted response. Some of the existing schemes for cyber intrusion detection in buildings include approaches that use machine learning (Tonejc et al. 2016) and rule-based approaches (Pan et al. 2014) to detect anomalies in the BMS communication network. While there is a handful literature on anomaly detection for building systems, combining communication network and physical system data could enable accurate differentiation between cyber-attacks and equipment or operational faults. Such distinction is needed to ensure appropriate control response to cyber threats and inform near-term deployment of security hardening measurements. The control options may include automated isolation and restoration (Jones et al. 2018), reconfigurable and adaptive control methods that modify the control algorithm to reflect the compromised building state and maintain essential performance level.

Power Outage Management

Power outages in buildings are either directly caused by weather-inflicted faults (e.g., high wind, snowstorm, hurricanes, etc.) or indirectly by equipment failures, operational errors, or adversarial activities. Local power supplies (e.g., onsite diesel generators, renewable energy resources, and storage) are usually utilized as emergency backups to power critical loads during the outage. To maximize operational

efficiency, minimize cost, and prolong the coverage time of the local power system, an advanced priority-driven control algorithm can be deployed to optimally dispatch the available local energy assets and effectively manage the changing load priorities in the building. Although power outages are stochastic events, the extreme weather-induced outages can be predicted (in a probabilistic manner) by correlating multiple sources of data including historical outage and weather data from diverse sources, e.g., land-based sensor measurement stations, radar, satellite, and national lightning detection network (Kezunovic et al. 2018). Such predictive capability would enable proactive controls that optimally plan and respond to events. A distributed generation asset can be actively managed through supply and load shifting. Grid power can be accumulated in actual or virtual storage (e.g., building pre-cooling) prior to the event and be optimally discharged during the outage event.

Emergency Egress

Many emergency situations (e.g., fire) in buildings call for immediate evacuation. In some countries, directional signage provides guidance for evacuation. Recently, intelligent egress systems have been developed that use occupancy information in conjunction with information from other building systems (e.g., fire safety and elevator systems) to determine the best path for evacuation. These systems are designed to maximize the occupants' safety while minimizing evacuation time by diverting evacuees to less-congested paths suggested by optimal routing algorithms (Desmet and Gelenbe 2014; Nguyen et al. 2019). For state-of-the-art buildings, real-time information of building occupancy can also be provided to first responders (such as fire fighters and facility personnel) to inform response tactics and accelerate search and rescue. Early approaches for occupancy estimation include a hybrid approach where sensor (e.g., motion sensor, video camera) data are combined with a dynamic model of people movement

to estimate occupancy using extended Kalman filter (Tomastik et al. 2008). Recent methods are leveraging smart wearable devices, ubiquitous availability of connectivity, and advancements in artificial intelligence. Indoor occupancy estimation and localization technologies are becoming prevalent and affordable for emergency evacuation and other normal operational benefits (Labeodan et al. 2015; Zafari et al. 2017).

Summary and Future Direction

The rising number of attacks against occupied commercial buildings in the last two decades has increased the urgency of protecting the building facilities, users, and (critical) operations from threats. New sensors are being developed to detect life safety threats. These threat sensors can be integrated with existing building control systems to enable rapid situation awareness and effective response to attacks. The Building Management System (BMS) serves as a cost-effective platform to enable the combined prowess of different building subsystems for threat detection and mitigation. For example, a fire or hazardous agent detection system can trigger an HVAC control system to reduce/shutdown ventilation to affected areas and/or inform a security system to release certain access doors for use as escape routes and/or stop passengers in an elevator at a safe level (e.g., ground level). This platform can also be used to enhance response to other emergency events such as hazardous contaminants, grid outages, and extreme weather. Future R&D is needed for holistic solutions that effectively coordinate the operation of the diverse building assets, threat confirmers, and notification strategies to maximize life safety and provide information to first responders.

Cyber-resilient control methods integrate cyber-attack detection and diagnostics with control strategies to minimize the attack impact on the building system performance. Timely and high detection accuracy becomes necessary for effective attack mitigation. In some cases, intelligent attackers may keep the attack process hidden and undetectable by closely following

the expected behavior of the system. Resilient control methods that achieve robustness to such undetectable stealthy anomaly are equally important. Future research is needed to explore the applicability of advance defense mechanisms for building domain. Examples include moving target defense mechanisms (Giraldo et al. 2019; Kanellopoulos and Vamvoudakis 2019) for deceiving and impeding a stealthy attacker and game theoretic methods (Bakker et al. 2019) for mitigating the influence of persistent attacker.

Engine Control

Luigi del Re¹ and Carlos Guardiola²

¹Johannes Kepler Universität, Linz, Austria

²Universitat Politècnica de València, Valencia, Spain

Abstract

Engine control is the enabling technology for efficiency, performance, reliability, and clean-

liness of modern vehicles equipped with a combustion engine for a wide variety of uses and users. It has also a paramount importance for many other engine applications like power plants. Engines are essentially chemical reactors, and the core task of engine control consists in preparing and starting the reaction (mixing the reactants and igniting the mixture) while the reaction itself is not controlled. The technical challenge derives from the combination of high complexity, wide range of conditions of use, performance requirements, significant time delays, and several constraints. In practice, engine control is to a large extent feed-forward control, feedback loops being used either for low-level control or for updating the feed forward. Industrial engine control is based on very complex structures calibrated experimentally, but there is a growing interest for model-based control with stronger feedback action, supported by the breakthrough of new computational and communication possibilities, as well as by the introduction of new sensors.

Keywords

Compression ignition · Emissions · Exhaust aftertreatment · Internal combustion engines · Spark ignition

Introduction

Even though electrification is becoming more important, most vehicles are moved by internal combustion engines (ICEs), and at least for some segments, like heavy duty, this is not expected to change for some time, mainly due to the energy density of fuels and to their well-established supply chain. ICEs provide traction power not only for road vehicles but also for off-road vehicles, ships, planes, and in some cases trains. The ICE is also a main element of alternative power plants as hybrid electrical vehicles (HEV) or may act as enablers for others, as in the case of their application as range extenders for plug-in hybrid electrical vehicles (PHEV).

The key function of an ICE is the conversion of chemical energy into mechanical energy, basically by oxidation, e.g., in the case of propane:

The chemical energy is first transformed into heat and converted by the ICE into mechanical energy through a thermodynamic cycle (Heywood 1988). The key task of engine control (Kiencke and Nielsen 2005) is to make sure that the reactants (fuel and oxygen) meet in the right proportion (“mixture formation”) and that the combustion is timely started (or “ignited”) to deliver the required torque at the engine crankshaft. Despite the apparent simplicity, the engine control has additional multiple tasks, the main ones being the following:

- To operate the system in an efficient way, adapting the engine operation to the varying ambient and use conditions while ensuring a smooth and agreeable torque delivery (or “driveability”).
- To keep the toxic by-products of the combustion below given threshold values, according to the certification levels required by the local legislations.
- To keep other undesired emissions (the so-called NVH - noise, vibration, and harshness) below given threshold values.
- To protect engine subsystems and limit the fatigue of components.
- To diagnose the operation of the system and to detect faults that could be a risk for the user or the environment.

It must be noticed that, beyond of the engine itself, the engine control is in charge to control, monitor, and coordinate many peripheral elements and subsystems. Relevant examples are the exhaust aftertreatment system, whose operation constraints the engine combustion settings, or the thermal management system. In a parallel way and significantly in vehicular applications, engine control must be coordinated with other powertrain and vehicular systems and with a plethora of

torque, braking, and driving assistance functions. The complexity of the vehicle architecture has exploded in recent years, and the propagation of the subsystem constraints for a safe operation to the supervisory layer represents one of the major challenges, as it also is to ensure the driveability of the system as a whole, which must be evaluated by subjective criteria. All these requirements have to be met for all vehicles of a production model in spite of production variability and under all relevant operating conditions, including all drivers, fuel specifications, road, traffic, and weather/altitude conditions.

Target Systems

The ICE may be classified according to its combustion process. While several processes are known, most of commercially available engines rely on two radically opposite concepts: spark-ignited (SI) and compression-ignited (CI) engines. The former, also referred as Otto engines, uses a nearly stoichiometric premixed charge of air and a low-reactivity fuel, and the combustion is triggered by an electrical spark, which allows an accurate control of the combustion phasing. The latter, known also as diesel engines, injects a high-reactivity fuel in a previously compressed inert cylinder charge, resulting in a diffusion flame with a low global equivalence ratio (i.e., fuel-to-air ratio). Figure 1 schematizes the operation of these two engine variants for the case of the more popular four-stroke implementation, which completes an engine cycle for every two turns of the crankshaft.

Figure 1 shows the basic setup of an ICE as CI and SI. In both cases, the main components of an ICE are air path, fuel path, combustion chamber, and exhaust path.

Basic air path layout is similar in SI and CI engines. While throttle valves are now present on both types, the nearly stoichiometric requirement for most conditions of SI engines implies that the air flow is frequently actively reduced by throttling, different from CI engines in which throttles are used only under special conditions.

Turbochargers are now widespread for both automotive CI and SI applications, as well as exhaust gas recirculation (EGR) circuits and, to a small extent, variable timing systems for the intake and exhaust valves of the combustion chamber.

CI combustion, which relies in a nonhomogeneous diffusion flame, requires a fuel with a high tendency to autoignition (diesel, oil, esters, etc.). In state-of-the-art engines, fuel is injected through the use of high-pressure injection systems (known as common rail injection systems), which allows a huge flexibility in the number, timing, and duration of the injection events. Differently, SI combustion is characterized by a flame front in a homogeneous mix and the use of high-octane fuels (gasoline, natural gas, liquefied petroleum gas, alcohols, etc.). Traditionally, the mixture was prepared outside of the combustion chamber, but most new SI engines (denoted as gasoline direct injection, GDI) are fitted with direct fuel injection systems similar to those of CI engines, which allow the mixture to be prepared in the cylinder and provide a certain degree of mix stratification.

Aftertreatment system layout depends on the engine combustion, since pollutant characteristics and oxygen excess in the exhaust gases restrict the selection of the aftertreatment elements. Three-way catalysts (TWC) are the widespread solution for SI engines, and in some cases, a gasoline particulate filter (GPF) is added; for CI engines, there is no universal solution, but a combination of diesel oxidation catalyst (DOC), diesel particulate filter (DPF), and selective catalytic reduction (SCR) has proven to be effective.

Roughly speaking, ICEs exhibit three time scales:

- Since ignition, combustion, exhaust, and intake processes at each cylinder occur once every thermodynamic cycle, many variables present significant variations along the cycle; for the case of a κ -cylinder four-stroke engine, the basic frequency is $\kappa \frac{n}{2}$ (which equals a 100 Hz for a four-cylinder engine at 3000 rpm) (Guardiola et al. 2020a).

Engine Control, Fig. 1 Operation of four-stroke CI (*top*) and SI (*bottom*) engines

- Some of the actuators must be synchronized with the cycle process (i.e., *crank angle synchronous*, as opposed to *time synchronous*) and allow a cycle-to-cycle control of the system, as it is the case of the fuel injection and spark ignition. On the other hand, air path dynamics are typically in the range of 0.5–5 Hz, due to mass accumulation in manifolds and turbocharger inertia.
- Finally, thermal processes of the engine and aftertreatment system are significantly slower, remarkably below 0.1 Hz, and many times with characteristic times of several minutes.

The Control Tasks

Engine systems are highly optimized; their control is no exception. The basic control task they address can be defined as the minimization of the average fuel consumption while providing the required torque and respecting the constraints on emissions (i.e., nitrogen oxides and dioxides (NO_x) and particulate matter (PM)), noise, temperature, etc. The legislators in different countries have defined test procedure, including a specified speed profile and corresponding emission limits. Figure 3 shows the progressive reduction of the limits and the speed profile used to assess this value.

Even if fuel consumption is not limited by law at a vehicle level (since only fleet averages must be satisfied), the associated key control problem can be stated as an optimal constrained control problem (besides the respect of instantaneous limits on actuators and states, e.g. maximum speed

of the turbocharger):

$$\min_{u(t)} \int_0^{t_{\max}} \dot{q}_f dt, \quad (2)$$

so that

$$v(t) = v_{\text{dem}}(t) \pm \Delta v \quad (3)$$

and

$$\int_0^{t_{\max}} \dot{q}_i dt \leq Q_i \quad (4)$$

where $u(t)$ are all available control inputs, $t_{\max}$ is the duration of the considered driving cycle (e.g., the WLTC cycle in Fig. 3), $v_{\text{dem}}(t)$ is the corresponding speed, Δv is the speed tolerance, $\dot{q}_f$ is the instantaneous fuel consumption, $\dot{q}_i$ is the each limited quantity (e.g., NO_x), and Q_i is the corresponding limit for the whole test. Notice that different countries use different certification cycles

E

Engine Control, Fig. 2 Basic system scheme of CI (left) and SI (right) engines: 1a Control of the injector opening; 1b injection premixing with air; 2 measurement of the engine temperature; 3 measurement of the engine rotational speed; 4 measurement of oxygen concentration in

the exhaust gases; 5a EGR valve; 5b throttle valve; 6a low-pressure EGR valve; 7a diesel exhaust aftertreatment (DOC, SCR, DPF); 7b SI engine aftertreatment (three-way catalyst); 8 SCR dosing control

(e.g., FTP cycle series in the United States), and the new engines are tested using the so-called real drive emissions (RDE), in which a sample vehicle is tested in real traffic conditions. This is a significant change in the certification approach, since the driving profile is not known beforehand: in RDE approach, only speed and acceleration metrics and general boundary conditions must be met for a driving profile to be considered as a valid test.

In practice, as already mentioned, other criteria must be considered as well, like NVH, and the control must be robust with respect to several parameters. For instance, most engines have several cylinders, and their combustion properties (including the properties of the injectors) are not exactly equal. On one side, engine control functions detect different torque production in the single cylinders and automatically compensate them; on the other side, some safety margins must be used to make sure that the real emissions will not pass the limit values. Even though this can be easily stated as an optimal problem as in Fig. 2 to Fig. 4, it is never solved in this way: on one side because there is no sufficiently good model which could be used to find the solution and on the other side in view of the enormous complexity.

In practice, different simpler subproblems are solved separately by heuristic descriptions –

typically maps – which can be tuned experimentally and even automatically (Schoggl et al. 2002); a modern engine control unit (ECU) can include up to 40,000 labels (parameters or maps). The resulting structure is mainly feed forward, with feedback loops typically used for control of actuators, primarily calibrated under laboratory conditions but with adaptation loops designed to correct parameters to take in account production and wear effects. Figure 4 shows an engine test bench setup with the engine control unit (ECU) and a calibration system.

While there is a wide agreement on the limits of this heuristic approach, there is no simple way out, as translating the actual ECU into a model-based structure would require an enormous effort. However, model-based parts are included, e.g., the wall-wetting compensation in the SI engines. In the following, we review some key parts of the combustion control.

Air Path Control

The main source of oxygen for the reaction of Eq. (1) is ambient air which contains about 21% oxygen. The engine – essentially a volumetric air pump – aspires air flow roughly proportional to the cylinder volume and the revolution speed of the engine. The amount of

Engine Control, Fig. 3 Left: different steps of limits of emissions per km as defined by the European Union (Euro 1 introduced in 1991 and Euro 6 from 2014). Right: New European Driving Cycle (NEDC)

gas entering the combustion chamber (referred as the cylinder charge), however, will depend also on temperature and pressure. This charge can be reduced by throttling (i.e., adding an additional flow resistance between the air intake and the combustion chamber, standard in SI engines) or increased by compressing the fresh air, most commonly by turbocharging. A turbocharger consists essentially of a turbine, which transforms part of the enthalpy of the exhaust gas into mechanical power, and a compressor, driven by this power to compress the fresh air on its way to the combustion chamber, thus increasing both its density and temperature. Turbocharger operation is typically controlled either directly (for instance, with variable vane angles) or indirectly, by bypass valves (known as waste gates) which deviate the gas flows in parallel to the turbine.

Variable valve timing (VVT) refers to several technologies aiming to modify valve timing and/or the valve lift. Some electrohydraulic systems already in the market allow a high flexibility of the valve timing with a cycle-to-cycle response time, while others rely on slower actuation over

camshaft relative phase or valve actuation chain. Some of the advantages of the fully flexible VVT systems are the control of the engine charge without intake manifold throttling, the effective compression ratio control, or the application of alternative engine cycles as Miller and Atkinson concepts through the modification of the compression and intake stroke. Finally, they may also serve for the cycle-to-cycle control of the cylinder charge.

Fresh air dilution may be used for controlling cylinder charge composition: if fresh ambient air is mixed with exhaust gases, resulting mix will have an oxygen concentration below 21% and an increased percentage of inert gases as CO₂ and moisture. This provides advantages in terms of NO_x reduction as it depends on adiabatic flame temperature which is strongly correlated with oxygen concentration. Therefore, in some engines, especially in CI engines, part of the combusted gases is recirculated to the combustion chamber (“exhaust gas recirculation,” EGR), as an active method for NO_x control. While EGR is typically realized at high pressures (as in Fig. 1), it may also be realized on the low pressure side

Engine Control, Fig. 4 Light-duty engine test bench with ECU and calibration system (JKU laboratory)

of turbine and compressor. Typically, the air path includes some coolers designed to increase gas density.

Air path control is designed to track dynamical references, for instance, the total fresh air mass flow (MAF) entering the cylinder and the corresponding manifold air pressure (MAP), but also other quantities are possible. The references are typically generated by the calibration engineers on the basis of tests. The control inputs of the air path are mostly the turbine (and possibly compressor) steering angle, the EGR, and – if available – throttle(s) set points. Most commonly used sensors include a mass flow meter (hot film sensor), rather slow and dynamically not reliable; pressure and temperature sensors; and sometimes the turbocharger speed as well. The actual position of the involved valves – throttle, turbine, or EGR – is usually measured, thus allowing cascade control and correcting the actuator hysteresis.

Fuel Path Control

The fuel path delivers the correct amount of fuel for the reaction (1). In almost every ICE, a rail is filled with fuel at a given pressure (from a few up to 400 bar for SI to about 3000 bar for CI), from which the required amount of fuel is injected into the cylinder. The injection can occur inside the combustion chamber (as for CI and GDI engines) or near the intake valve (“port injection”) for standard SI engines.

The injection amount corresponds roughly to the desired torque but is always constrained taking into account the available oxygen mass. In SI engines with three-way catalyst, the fuel injection is given by the stoichiometric condition, i.e., the ratio between the fuel quantity which can be perfectly burnt and the injected fuel, the so-called λ -factor, is exactly 1 ($\lambda > 1$ is called lean mixture or air excess and is common for diesel and GDI engines but prevents the use of a TWC). λ control uses an oxygen sensor in the exhaust to determine the actual λ for instantaneous control and if appropriate slowly corrects the injection tables. In CI and GDI, the maximum fuel injection is limited to prevent smoke formation, typically by tables, even though λ control can be and is partly used (Amstutz and del Re 1995). Manufacturing

discrepancies and aging are compensated by the use of the λ control, while individual cylinder balancing is usually performed by the analysis of the variation of the engine speed along the combustion cycle.

In SI engines with port injection, the liquid fuel is injected near the inlet valve and is expected to vaporize due to the local temperature and pressure conditions. During load changes, however, it can happen that part of the fuel is not vaporized, remains on the duct wall (“wall wetting”), and vaporizes at a later time, leading in both cases to a deviation from the expected values (Turin and Geering 1995), which must be compensated by the injection control.

Direct injection systems allow a more direct control of the injection event and usually allow several injections per cylinder and cycle. Injection in CI engines is typically split in a main injection for torque, a pilot injection for NVH control, and sometimes also a postinjection for emission control or regeneration of aftertreatment devices. In GDI engines, injection may allow an active control of the combustion mode: if the injection is performed during the intake stroke, a homogeneous mix is formed, and the combustion is like in conventional SI engines; if the injection, sometimes split in a couple of shorter injections, is delayed, the mix may be stratified with advantages in terms of fuel efficiency. This latter strategy needs a careful coordination of the injection and ignition control.

Ignition

Once the combustion chamber is filled, the combustion can be started. In traditional SI and GDI, combustion is started by a spark, leading to a flame front which propagates through the whole combustion chamber. Because of differences in the flame propagation, these engines are affected by significant cycle-to-cycle variability. Spark timing and energy are used for reducing this variability. In challenging situations, multiple consecutive sparks may be used; very few SI engines have a second spark plug to better control the ignition process.

In addition to the cycle-to-cycle variability, faulty cycles may occur. Misfires may be related with λ very different from 1 or problems in the

spark plugs. Misfires must be detected as they significantly impact pollutant emissions. Usual detection strategy relies in analyzing the in-cycle variation of the crankshaft acceleration, which allows isolating faulty cycles and detects persistent faults.

Under some circumstances, e.g., high temperature, an undesired autoignition (“knock”) can occur with potentially catastrophic consequences for the engine durability and also unconventional NVH. To cope with this, SI engines have vibration sensors whose output is used to modify the engine operation, in particular the spark timing, to prevent knock occurrence. In such engines, the spark timing is continuously varied for each cycle: it is slightly advanced with respect to the previous cycle if no knock is detected, while it is delayed if previous cycle was classified as a knocking cycle. Such simple control allows to adapt the engine to the fuel quality and the varying ambient and use conditions.

In CI engines, there is no direct actuator for the ignition, since the combustion is a consequence of the self-ignition of the fuel as it is injected. Thus, injection settings and charge oxygen concentration crucially impact the combustion timing and the pollutant formation. While in-cylinder pressure sensors can provide valuable information about the combustion, most engines rely on a collection of lookup tables for adapting the settings to the use and operative conditions.

Aftertreatment

Pollutant formation is the undesirable side effect of combustion. In a perfect combustion, as in (1), the combustion will only produce water and CO_2 (which is not considered as a pollutant in the classical sense as it is the natural product of a complete combustion); however, due to partial combustion or side reactions, additional species may occur. Incomplete fuel burnt yields to hydrocarbons (HC), carbon monoxide (CO), and particulate matter (PM), which is the aggregation of soot and heavy HC from fuel or lubricant partial combustion. Even if much effort is spent on reducing their formation, this is almost never sufficient for reaching regulated limits, so additional aftertreatment equipment is used. Table 1 gives an

overview over the most common aftertreatment systems as well as over their control aspects.

Modern automotive engines usually combine a series of systems for the control of the more relevant pollutant species. For the case of the SI engines, operating in nearly stoichiometric combustion, three-way catalysts (TWC) provide a compact and cost-effective solution for the joint control of HC, CO, and NO_x . The catalyst is able to reduce NO_x and, at the same time, oxidizes CO and HC; it also has the capacity of storing a certain amount of excess oxygen, so it can control short excursions of the systems out of the specified control reference. For TWC to be effective, it requires $\lambda \approx 1$.

For the case of CI engines, which operate with excess oxygen, aftertreatment is more challenging. While diesel oxidation catalysts (DOC) are able to oxidize CO and HC making use of the oxygen in the exhaust, NO_x needs an active approach. Selective catalytic reduction (SCR) uses an injection of a mix of water and urea for generating ammonia (NH_3) as reductor agent for abating the NO_x . Note that a low value of the urea dosing will yield NO_x emissions, while an excess will imply the existence of ammonia slip. Optimal urea dosing is the main difficulty for SCR: not only the trade-off between NH_3 slip and NO_x conversion must be considered, but also the urea consumption must be kept controlled for avoiding unscheduled refilling. Closed-loop control is needed for fulfilling the regulation and diagnosis, and NO_x sensors are already in production. SCR systems may be controlled despite the existence of several chemical species in the exhaust and the cross sensitivity of NO_x sensors to NH_3 slip (Guardiola et al. 2020b).

An important problem of the current aftertreatment technology is the need to reach a certain temperature for the catalyst to be effective, known as light-off temperature (Guardiola et al. 2018b). In order to avoid excessive emissions during cold phases of the engine operation, some elements may be included with storing capacities. For example, DOC is usually able to store a certain amount of HC at low temperature; the HCs are later burnt with exhaust excess oxygen when the catalyst meets the light-off

Engine Control, Table 1

Main exhaust
aftertreatment systems

System	Purpose	Control targets
Three-way catalyst	Reduction of HC, CO, and NO _x by more than 98%	Achieve fast and maintain operating temperature and keep $\lambda = 1$
Oxidation catalyst	Reduction of HC and CO, partly of PM	Achieve fast and maintain operating temperature and keep $\lambda > 1$
Particulate filter	Traps PM	Check trap state and regenerate by increasing exhaust temperature for short time if needed
NO _x lean trap	Traps NO _x	Estimate trap state and shift combustion to CO rich when required
Selective catalytic reduction	Reduces NO _x	Estimate required quantity of additional reactant (urea) and dose it

temperature. Lean NO_x traps (LNT) are able to store NO_x at low temperature, which are later released when the SCR reaches the light-off temperature or alternatively reduced using excess CO and HC generated by modifications on the air-to-fuel ratio control during the so-called regeneration phase. It must be noticed that a same catalyst brick can be designed for combining several of the aforementioned functionalities.

Finally, PM is usually filtered through particulate filters in CI (DPF) and GDI (GPF) engines. Particulate filters accumulate the generated PM and, depending on the engine kind, must be actively regenerated when a given amount of particulates is stored. In some engines, exhaust temperature is sufficient for a periodic burnt of the accumulated PM. For the case of modern diesel engines, DPF regeneration makes use of delayed postinjections producing excess HC which are burnt at the DOC rising the exhaust temperature above 600 °C. Closed-loop control of the exhaust temperature is usually implemented for controlling these regeneration events, which are usually scheduled according to a combination of models and pressure drop measurements. Note that regenerating a filter with an excessive amount of particulates may result in excessive temperature, destroying the filter itself or more commonly other catalysts in the exhaust line (as the SCR).

Cranking and Idle Speed

Initially, the engine is cranked by the starter until a relatively low speed, and then, injection starts bringing the engine to the minimum operational speed. This operation can be performed without difficulty in favorable conditions (warm engine and ambient conditions around the standard), but it can be challenging in other situations as it can lead to emission spikes which could not be withhold by the exhaust aftertreatment system. Thus, a specific strategy is necessary that is robust enough so that a proper engine start occurs even when the conditions are not favorable. This action is further conditioned by the reduced power of typical engine starters, which are not able to rotate the engine at a high speed (in general, half of the idle speed is usually not exceeded).

During the cranking process, special control actions are set into place with the sole purpose of obtaining combustion in the first cycles; once rotational speed is above a given threshold, engine stall is unlikely, and warm-up process may start. Some of the strategies articulated during these first cycles include nonconventional fueling strategies able to compensate for the very cold intake and cylinder walls, use of a train of sparks in SI engines, and wide open throttle valve.

Normally, an ICE is expected to provide a torque to the driveline, speed being the result of the balance between it and the load. In idle control however, no torque is transmitted to the driveline: the engine is declutched, and it is expected

to remain stable in spite of possible changes of local loads (like cabin climate control or engine ancillary systems). This is essentially a robust control problem (Hrovat and Sun 1997).

In many modern engines, idling is avoided as much as possible, and the engine is stopped when no torque is demanded. This strategy, denoted as stop-start, requires frequent cranking of the engine and usually needs a better specification of the starter. With a correct thermal management, controlling the position of the crankshaft at the engine stop, and the right injection settings, modern systems are able to achieve combustion in the first cycle for avoiding misfires resulting in emission and NVH level increase.

Thermal Management

Despite being one of the main loss flows in the ICE, heat has become a precious resource during engine operation. Specific actions are to be implemented during warm-up phase or when extra heat flow is required for aftertreatment regeneration. Engine heat is also required for other purposes (like defrosting of windshields in cold climates). In this sense, stop-start adds additional complexity from the thermal management point of view, as it is the integration of the engine into HEV powertrains, resulting in the engine to be stop for extended periods. Electrical heated systems can add an extra degree of freedom and can be used for accelerating the light-off temperature of different aftertreatment devices, but they heavily impact overall efficiency.

All main properties of engines are strongly affected by their temperature, which depends on the varying load conditions. Engine operation is typically optimal for a relatively narrow temperature range; the same is even more critical for the exhaust aftertreatment system. On the other hand, control settings must be significantly modified when the engine is operating far from its reference temperature. Thus, the engine control system has two main tasks: bringing the engine and the exhaust aftertreatment system as fast as possible into the target temperature range and taking into account deviation from this target. The first task is performed both by control of the cooling circuit and by specific

combustion-related measures, the second one by taking the measured or estimated temperature as input for the controllers.

A number of measures are implemented during the warm-up operation of the engine: valves in the cooling system are set to avoid heat transfer to the ambient, and specially designed combustion modes with excess exhaust heat – even if impacting fuel efficiency – are set. Note that if the aftertreatment is not able to store the pollutants while the catalysts are below the light-off temperature, this will critically impact pollutant emission levels; this is the case of SI engines simply relying on a TWC.

New Trends

Over the past decades, the importance of the engine control system has been increasing enormously, and this trend is expected to continue. The importance of electronic control in the engine will be reinforced by the following:

- Increase in the number of electronically controlled systems: more and more systems are managed by the control unit, and it is foreseeable that in the future, the number of electronically controlled actuators will increase further. Electrification is steadily reaching elements that have historically been mechanically actuated, such as the lubricant pump or the coolant pump, adding new degrees of freedom. In parallel with the grow in actuators, the list of available sensors is steadily growing.
- The increase in engine flexibility requirements, which must be able to adapt to different operating modes and possibly different fuels, all with increased robustness and self-diagnostic capacity.
- Increased coordination among the different vehicle systems. Within this framework and in relation to the layered structure of the control software, it is possible that the control of different components is carried out in a single controller or, more likely, in distributed systems that share high-level information through data buses.

- Increased coordination among vehicles, through infrastructure-to-vehicle (I2V) and vehicle-to-vehicle (V2V) communication, which may allow for traffic management actions, improved security, cooperative adaptive cruise control (CACC), or even self-guided vehicle caravan systems (referred in literature as “platooning”).

Against this background, it is expected that both the current control system structure and the calibration process associated with it will undergo sustained changes. In order to simplify the calibration process and to allow optimal control of the system, two lines of evolution (not mutually exclusive) can be observed:

- Development of model-based control systems, which are based on the existence of a model (physical or mathematical) that describes the operation of the engine. The model can be used to derive the laws of control, or it can be used as a prediction model within a predictive control system (del Re et al. 2010). The improvements in this approach reside, on the one hand, in reducing the number of tests required during calibration and, on the other one, in the possibility of deriving optimal control laws based on the prediction provided by the model. The first advantage is especially evident when using physical models (as mean value engine models, MVEM), since the model contains a description of the physical phenomena and therefore needs less identification effort (Alberer et al. 2012). Some model-based controls have already found their way into the ECU, and the academy has shown in several occasions that model-based control is able to achieve better performance, but it has not yet been shown how this could comply with other industrialization requirements. In many cases, models are included in the ECU for inferring some of the variables that are not directly measured (i.e., “virtual sensors”), but are not integrated in predictive controls (Guardiola et al. 2017).
- Use of adaptive systems so that the control system is able to improve its performance

based on measurements provided by the sensors and through certain learning laws. An adaptive system would allow to absorb manufacturing variability and the effects of drift and aging and adapting to real-use conditions (Guardiola et al. 2016). In addition, it could be used to adapt models in real time, which can be utilized for use in the control system or for engine diagnostics. Data connectivity makes it possible to manage this learning in a cloud environment and access data of different units (as opposed to embedded ECU approach); artificial intelligence techniques can be used for processing and clustering the huge data stream at a fleet level. Over-the-air ECU firmware update is already a possibility, so embedded control unit software can be updated as new information is available. While unsupervised learning for control system stands as a difficulty because of safety concerns, significant advancements are expected in this direction. Also regulation bodies are skeptical in view of possible abuse to circumvent tests, as shown by recent events involving a major manufacturer.

Estimation and Control over Networks

Vijay Gupta
Department of Electrical Engineering, University of Notre Dame, Notre Dame, IN, USA

Abstract

Estimation and control of systems when data is being transmitted across nonideal communication channels has now become an important research topic. While much progress has been made in the area over the last few years, many open problems still remain. This entry summarizes some

results available for such systems and points out a few open research directions. Two popular channel models are considered – the analog erasure channel model and the digital noiseless model. Results are presented for both the multichannel and multisensor settings.

Keywords

Analog erasure channel · Digital noiseless channel · Networked control systems · Sensor fusion

Introduction

Networked control systems refer to systems in which estimation and control is done across communication channels. In other words, these systems feature data transmission among the various components – sensors, estimators, controllers, and actuators – across communication channels that may delay, erase, or otherwise corrupt the data. It has been known for a long time that the presence of communication channels has deep and subtle effects. As an instance, an asymptotically stable linear system may display chaotic behavior if the data transmitted from the sensor to the controller and the controller to the actuator is quantized. Accordingly, the impact of communication channels on the estimation/control performance and design of estimation/control algorithms to counter any performance loss due to such channels have both become areas of active research.

Preliminaries

It is not possible to provide a detailed overview of all the work in the area. This entry attempts to summarize the flavor of the results that are available today. We focus on two specific communication channel models – analog erasure channel and the digital noiseless channel. Although other channel models, e.g., channels that introduce delays or additive noise, have been consid-

ered in the literature, these models are among the ones that have been studied the most. Moreover, the richness of the field can be illustrated by concentrating on these models.

An analog erasure channel model is defined as follows. At every time step k , the channel supports as its input a real vector $i(k) \in \mathbf{R}^t$ with a bounded dimension t . The output $o(k)$ of the channel is determined stochastically. The simplest model of the channel is when the output is determined by a Bernoulli process with probability p . In this case, the output is given by

$$o(k) = \begin{cases} i(k-1) & \text{with probability } 1-p \\ \phi & \text{otherwise,} \end{cases}$$

where the symbol ϕ denotes the fact that the receiver does not obtain any data at that time step and, importantly, recognizes that the channel has not transmitted any data. The probability p is termed the erasure probability of the channel. More intricate models in which the erasure process is governed by a Markov chain, or by a deterministic process, have also been proposed and analyzed. In our subsequent development, we will assume that the erasure process is governed by a Bernoulli process.

A digital noiseless channel model is defined as follows. At every time step k , the channel supports at its input one out of 2^m symbols. The output of the channel is equal to the input. The symbol that is transmitted may be generated arbitrarily; however, it is natural to consider the channel as supporting m bits at every time step and the specific symbol transmitted as being generated according to an appropriately design quantizer. Once again, additional complications such as delays introduced by the channel have been considered in the literature.

A general networked control problem consists of a process whose states are being measured by multiple sensors that transmit data to multiple controllers. The controllers generate control inputs that are applied by different actuators. All the data is transmitted across communication channels. Design of control inputs when multiple controllers are present, even without the

presence of communication channels, is known to be hard since the control inputs in this case have dual effect. It is, thus, not surprising that not many results are available for networked control systems with multiple controllers. We will thus concentrate on the case when only one controller and actuator is present. However, we will review the known results for the analog erasure channel and the digital noiseless channel models when (i) multiple sensors observe the same process and transmit information to the controller and (ii) the sensor transmits information to the controller over a network of communication channels with an arbitrary topology.

An important distinction in the networked control system literature is that of one-block versus two-block designs. Intuitively, the one-block design arises from viewing the communication channel as a perturbation to a control system designed without a channel. In this paradigm, the only block that needs to be designed is the receiver. Thus, for instance, if an analog erasure channel is present between the sensor and the estimator, the sensor continues to transmit the measurements as if no channel is present. However, the estimator present at the output of the channel is now designed to *compensate* for any imperfections introduced by the communication channel. On the other hand, in the two-block design paradigm, both the transmitter and the receiver are designed to optimize the estimation or control performance. Thus, if an analog erasure channel is present between the sensor and the estimator, the sensor can now transmit an appropriate function of the information it has access to. The transmitted quantity needs to satisfy the constraints introduced by the channel in terms of the dimensions, bit rate, power constraints, and so on. It is worth remembering that while the two-block design paradigm follows in spirit from communication theory where both the transmitter and the receiver are design blocks, the specific design of these blocks is usually much more involved than in communication theory. It is not surprising that in general performance with two-block designs is better than the one-block designs.

Analog Erasure Channel Model

Consider the usual LQG formulation. A linear process of the form

$$x(k+1) = Ax(k) + Bu(k) + w(k),$$

with state $x(k) \in \mathbf{R}^d$ and process noise $w(k)$ is controlled using a control input $u(k) \in \mathbf{R}^m$. The process noise is assumed to be white, Gaussian, zero mean, with covariance Σ_w . The initial condition $x(0)$ is also assumed to be Gaussian and zero mean with covariance Π_0 . The process is observed by n sensors, with the i -th sensor generating measurements of the form

$$y_i(k) = C_i x(k) + v_i(k),$$

with the measurement noise $v_i(k)$ assumed to be white, Gaussian, zero mean, with covariance $\Sigma_{v_i}^i$. All the random variables in the system are assumed to be mutually independent. We consider two cases:

- If $n = 1$, the sensor communicates with the controller across a network consisting of multiple communication channels connected according to an arbitrary topology. Every communication channel is modeled as an analog erasure channel with possibly a different erasure probability. The erasure events on the channels are assumed to be independent of each other, for simplicity. The sensor and the controller then form two nodes of a network each edge of which represents a communication channel.
- If $n > 1$, then every sensor communicates with the controller across an individual communication channel that is modeled as an analog erasure channel with possibly a different erasure probability. The erasure events on the channels are assumed to be independent of each other, for simplicity.

The controller calculates the control input to optimize a quadratic cost function of the form

$$J_K = E \left[\sum_{k=0}^{K-1} \left(x^T(k) Q x(k) + u^T(k) R u(k) \right) + x^T(K) P_K x(K) \right].$$

All the covariance matrices and the cost matrices Q , R , and P_K are assumed to be positive definite. The pair (A, B) is controllable and the pair (A, C) is observable, where C is formed by stacking the matrices C_i 's. The system is said to be stabilizable if there exists a design (within the specified one-block or two-block design framework) such that the cost $\lim_{K \rightarrow \infty} \frac{1}{K} J_K$ is bounded.

A Network of Communication Channels

We begin with the case when $N = 1$ as mentioned above. The one-block design problem in the presence of a network of communication channels is identical to the one-block design as if only one channel were present. This is because the network can be replaced by an “equivalent” communication channel with the erasure probability as some function of the reliability of the network. This can lead to poor performance, since the reliability may decrease quickly as the network size increases. For this reason, we will concentrate on the two-block design paradigm.

The two-block design paradigm permits the nodes of the network to process the data prior to transmission and hence achieve much better performance. The only constraint imposed on the transmitter is that the quantity that is transmitted is a causal function of the information that the node has access to, with a bounded dimension. The design problem can be solved using the following steps. The first step is to prove that a separation principle holds if the controller knows the control input applied by the actuator at every time step. This can be the case if the controller transmits the control input to the actuator across a perfect channel or if the control input is transmitted across an analog erasure channel but the actuator can transmit an acknowledgment to the controller. For simplicity, we assume that the controller transmits the control input to the actu-

ator across a perfect channel. The separation principle states that the optimal performance is achieved if the control input is calculated using the usual LQR control law, but the process state is replaced by the minimum mean squared error (MMSE) estimate of the state. Thus, the two-block design problem needs to be solved now for an optimal *estimation* problem.

The next step is to realize that for any allowed two-block design, an upper bound on estimation performance is provided by the strategy of every node transmitting every measurement it has access to at each time step. Notice that this strategy is not in the set of allowed two-block designs since the dimension of the transmitted quantity is not bounded with time. However, the same estimate is calculated at the decoder if the sensor transmits an estimate of the state at every time step and every other node (including the decoder) transmits the latest estimate it has access to from either its neighbors or its memory. This algorithm is recursive and involves every node transmitting a quantity with bounded dimension, however, since it leads to calculation of the same estimate at the decoder, and is, thus, optimal. It is worth remarking that the intermediate nodes do not require access to the control inputs. This is because the estimate at the decoder is a linear function of the control inputs and the measurements: thus, the effect of control inputs in the estimate can be separated from the effect of the measurements and included at the controller. Moreover, as long as the closed loop system is stable, the quantities transmitted by various nodes are also bounded. Thus, the two-block design problem can be solved.

The stability and performance analysis with the optimal design can also be performed. As an example, a necessary and sufficient stabilizability condition is that the inequality

$$p_{\max\text{cut}}\rho(A)^2 < 1,$$

holds, where $\rho(A)$ is the spectral radius of A and $p_{\max\text{cut}}$ is the max-cut probability evaluated as follows. Generate cut-sets from the network by dividing the nodes into two sets – a source set containing the sensor and a sink set containing

the controller. For each cut-set, obtain the cut-set probability by multiplying the erasure probabilities of the channels from the source set to the sink set. The max-cut probability is the maximum such cut-set probability. The necessity of the condition follows by recognizing that the channels from the source set to the sink set need to transmit data at a high enough rate even if the channels within each set are assumed not to erase any data. The sufficiency of the condition follows by using the Ford-Fulkerson algorithm to reduce the network into a collection of parallel paths from the sensor to the controller such that each path has links with equal erasure probability and the product of these probabilities for all paths is the max-cut probability. More details can be found in Gupta et al. (2009a).

Multiple Sensors

Let us now consider the case when the process is observed using multiple sensors that transmit data to a controller across an individual analog erasure channel. A separation principle to reduce the control design problem into the combination of an LQR control law and an estimation problem can once again be proven. Thus, the two-block design for the estimation problem asks the following question: what quantity should the sensors transmit such that the decoder is able to generate the optimal MMSE estimate of the state at every time step, given all the information the decoder has received till that time step. This problem is similar to the track-to-track fusion problem that has been studied since the 1980s and is still open for general cases (Chang et al. 1997). Suppose that at time k , the last successful transmission from sensor i happened at time $k_i \leq k$. The optimal estimate that the decoder can ever hope to achieve is the estimate of the state $x(k)$ based on all measurements from the sensor 1 till time k_1 , from sensor 2 till time k_2 , and so on. However, it is not known whether this estimate is achievable if the sensors are constrained to transmit real vectors with a bounded dimension. A fairly intuitive encoding scheme is if the sensors transmit the *local* estimates of the state based on their own measurements. However, it is known that the *global* estimate cannot, in general, be

obtained from local estimates because of the correlation introduced by the process noise. If erasure probabilities are zero, or if the process noise is not present, then the optimal encoding schemes are known. Another case for which the optimal encoding schemes are known is when the estimator sends back acknowledgments to the encoders.

Transmitting local estimates does, however, achieve optimal stability conditions as compared to the conditions obtained from the optimal (unknown) two-block design (Gupta et al. 2009b). As an example, the necessary and sufficient stability conditions for the two sensor cases are given by

$$\begin{aligned} p_1 \rho(A_1)^2 &< 1 \\ p_2 \rho(A_2)^2 &< 1 \\ p_1 p_2 \rho(A_3)^2 &< 1, \end{aligned}$$

where p_1 and p_2 are erasure probabilities from sensors 1 and 2, respectively, $\rho(A_1)$ is the spectral radius of the unobservable part of the matrix A from the second sensor, $\rho(A_2)$ is the spectral radius of the unobservable part of the matrix A from the first sensor, and $\rho(A_3)$ is the spectral radius of the observable part of the matrix A from both the sensors. The conditions are fairly intuitive. For instance, the first condition provides a bound on the rate of increase of modes for which only sensor 1 can provide information to the controller, in terms of how reliable the communication channel from the sensor 1 is.

Digital Noiseless Channels

Similar results as above can be derived for the digital noiseless channel model. For the digital noiseless channel model, it is easier to consider the system without either measurement or process noises (although results with such noises are available). Moreover, since quantization is inherently highly nonlinear, results such as separation between estimation and control are not available. Thus, encoders and controllers that optimize a cost function such as a quadratic performance metric are not available even for the single sensor or channel case. Most available results thus

discuss stabilizability conditions for a given data rate that the channels can support.

While early works used the one-block design framework to model the digital noiseless channel as introducing an additive white quantization noise, that framework obscures several crucial features of the channel. For instance, such an additive noise model suggests that at any bit rate, the process can be stabilized by a suitable controller. However, a simple argument can show that is not true. Consider a scalar process in which at time k , the controller knows that the state is within a set of length $l(k)$. Then, stabilization is possible only if $l(k)$ remains bounded as $k \rightarrow \infty$. Now, the evolution of $l(k)$ is governed by two processes: at every time step, this uncertainty can be (i) decreased by a factor of at most 2^m due to the data transmission across the channel and (ii) increased by a factor of a (where a is the process matrix governing the evolution of the state) due to the process evolution. This implies that for stabilization to be possible, the inequality $m \geq \log_2(a)$ must hold. Thus, the additive noise model is inherently wrong. Most results in the literature formalize this basic intuition above (Nair et al. 2007).

A Network of Communication Channels

For the case when there is only one sensor that transmits information to the controller across a network of communication channels connected in arbitrary topology, an analysis similar to that done for analog erasure channels can be performed (Tatikonda 2003). A max-flow min-cut like theorem again holds. The stability condition now becomes that for any cut-set

$$\sum R_j > \sum_{\text{all unstable eigenvalues}} \log_2(\lambda_i),$$

where $\sum R_j$ is the sum of data rates supported by the channels joining the source set to sink set for any cut-set and λ_i are the eigenvalues of the process matrix A . Note that the summation on the right hand side is only over the unstable eigenvalues, since no information needs to be transmitted about the modes that are stable in open loop.

Multiple Sensors

The case when multiple sensors transmit information across an individual digital noiseless channel to a controller can also be considered. For every sensor i , define a rate vector $\{R_{i_1}, R_{i_2}, \dots, R_{i_d}\}$ corresponding to the d modes of the system. If a mode j cannot be observed from the sensor i , set $R_{ij} = 0$. For stability, the condition

$$\sum_i R_{ij} \geq \max(0, \lambda_j),$$

for every mode j must be satisfied. All such rate vectors stabilize the system.

Summary and Future Directions

This entry provided a brief overview of some results available in the field of networked control systems. Although the area is seeing intense research activity, many problems remain open. For control across analog erasure channels, most existing results break down if a separation principle cannot be proved. Thus, for example, if control packets are also transmitted to the actuator across an analog erasure channel, the LQG optimal two-block design is unknown. There is some recent work on analyzing the stabilizability under such conditions (Gupta and Martins 2010), but the problem remains open in general. For digital noiseless channels, controllers that optimize some performance metric are largely unknown. Considering more general channel models is also an important research direction (Martins and Dahleh 2008; Sahai and Mitter 2006).

Estimation for Random Sets

Ronald Mahler

Random Sets LLC, Eagan, MN, USA

Abstract

The *random set* (RS) concept generalizes that of a random vector. It permits the mathematical modeling of random systems that can be interpreted as *random patterns*. Algorithms based on RSs have been extensively employed in image processing. More recently, they have found application in multitarget detection and tracking and in the modeling and processing of human-mediated information sources. The purpose of this article is to briefly summarize the concepts, theory, and practical application of RSs.

Keywords

Random sets · Stochastic geometry · Point processes · Image processing · Multitarget tracking

Introduction

In ordinary signal processing, one models physical phenomena as “sources,” which generate “signals” obscured by random “noise.” The sources are to be extracted from the noise using optimal estimation algorithms. Random set (RS) theory was devised about 40 years ago by mathematicians who also wanted to construct optimal estimation algorithms. The “signals” and “noise” that they had in mind, however, were *geometric patterns in images*. The resulting theory, *stochastic geometry*, is the basis of the “morphological operators” commonly employed today in image-processing applications. It is also the basis for the theory of RSs. An important special case of RS theory, the theory of *random finite sets* (RFSs), addresses problems in which the patterns of interest consists of a finite number of points. It is the theoretical basis of many modern medical and other image-processing algorithms. In recent years, RFS theory has found application to the problem of detecting, localizing, and tracking unknown numbers of unknown, evasive point targets. Most recently and perhaps most surprisingly, RS theory provides a theoretically rigorous way of addressing “signals” that are *human-mediated*, such as natural-language statements and inference rules. The breadth of RS theory is suggested in the various chapters of Goutsias et al. (1997).

The purpose of this article is to summarize the RS and RFS theories and their applications. It is organized as follows: A simple example, Mathematics of Random Sets, Random Sets and Image Processing, Random Sets and Multitarget Processing, Random Sets and Human-Mediated Data, Summary and Future Directions, Cross-References, and Recommended Reading.

A Simple Example

To illustrate the concept of a RS, let us begin by examining a simple example: *locating stars in the nighttime sky*. We will proceed in successively more illustrative steps.

Locating a single non-dim star (estimating a random point). When we try to locate a star, we are trying to estimate its actual position—its “state” $\mathbf{x} = (\alpha_0, \theta_0)$ —in terms of its azimuth angle α_0 and elevation angle θ_0 . When the star is dim but not too dim, its apparent position will vary slightly. We can estimate its position by averaging many measurements—i.e., by applying a *point estimator*.

Locating a very dim star (estimating an RS with at most one element). Assume that the star is so dim that, when we see it, it might be just a momentary visual illusion. Before we can estimate its position, we must *first estimate whether or not it exists*. We must record not only its apparent position $\mathbf{z} = (\alpha, \theta)$ (if we see it) but its *apparent existence* ε , with $\varepsilon = 1$ (we saw it) or $\varepsilon = 0$ (we didn’t). Averaging ε over many observations, we get a number q between 0 and 1. If $q > \frac{1}{4}$ (say), we could declare that the star probably actually is a star; and then we could average the non-null observations to estimate its position.

Locating multiple stars (estimating an RFS). Suppose that we are trying to locate *all* of the stars in some patch of sky. In some cases, two dim stars may be so close that they are difficult to distinguish. We will then collect three kinds of measurements from them: $Z = \emptyset$ (didn’t see either star), $Z = \{(\alpha, \theta)\}$ (we saw one or the other), or $Z = \{(\alpha_1, \theta_1), (\alpha_2, \theta_2)\}$ (saw both). The total collected measurement in the patch of sky is a finite set $Z = \{\mathbf{z}_1, \dots, \mathbf{z}_m\}$ of point measurements with $\mathbf{z}_j = (\theta_j, \alpha_j)$, where each $\mathbf{z}_i$ is random, where m is random, and where $m = 0$ corresponds to the null measurement $Z = \emptyset$.

Locating multiple stars in a quantized sky (estimation using imprecise measurements).

Suppose that, for computational reasons, the patch of sky must be quantized into a finite number of hexagonal-shaped cells, $c_1, \dots, c_M$. Then the measurement from any star is not a specific point $\mathbf{z}$ but instead the cell c that contains $\mathbf{z}$. The measurement c is *imprecise*—a randomly varying hexagonal cell c . There are two ways of thinking about the total measurement collection. First, it is a finite set $Z = \{c'_1, \dots, c'_m\} \subseteq \{c_1, \dots, c_M\}$ of cells. Second, it is the union $Z = c'_1 \cup \dots \cup c'_m$ of all of the observed cells—i.e., it is a *geometrical pattern*.

Locating multiple stars over an extended period of time (estimating multiple moving targets). As the night progresses, we must continually redetermine the existence and positions of each star—a process called *multitarget tracking*. We must also account for appearances and disappearances of the stars in the patch—i.e., for *target death and birth*.

Mathematics of Random Sets

The purpose of this section is to sketch the elements of the theory of random sets. It is organized as follows: General Theory of Random Sets, Random Finite Sets (Random Point Processes), and Stochastic Geometry. Of necessity, the material is less elementary than in later sections.

General Theory of Random Sets

Let $\mathfrak{Y}$ be a topological space—for example, an N -dimensional Euclidean space $\mathbb{R}^N$. The *power set* $2^{\mathfrak{Y}}$ of $\mathfrak{Y}$ is the class of all possible subsets $S \subseteq \mathfrak{Y}$. Any subclass of $2^{\mathfrak{Y}}$ is called a “hyperspace.” The “elements” or “points” of a hyperspace are thus actually subsets of some other space. For a hyperspace to be of interest, one must extend the topology on $\mathfrak{Y}$ to it. There are many possible topologies for hyperspaces (Michael 1950). The most well-studied is the *Fell-Matheron topology*, also called the “hit-and-miss” topology (Matheron 1975). It is applicable when $\mathfrak{Y}$ is Hausdorff, locally compact, and completely separable. It topologizes only

the hyperspace $\mathfrak{c}(2^{\mathfrak{Y}})$ of all *closed* subsets C of $\mathfrak{Y}$. In this case, a *random* (closed) set Θ is a measurable mapping from some probability space into $\mathfrak{c}(2^{\mathfrak{Y}})$.

The Fell-Matheron topology’s major strength is its relative simplicity. Let “ $\Pr(\mathcal{E})$ ” denote the probability of a probabilistic event $\mathcal{E}$. Then normally, the probability law of Θ would be described by a very abstract probability measure $p_{\Theta}(O) = \Pr(\Theta \in O)$. This measure must be defined on the Borel-measurable subsets $O \subseteq \mathfrak{c}(2^{\mathfrak{Y}})$, with respect to the Fell-Matheron topology, where O is itself a class of subsets of $\mathfrak{Y}$. However, define the *Choquet capacity functional* by $c_{\Theta}(G) = \Pr(\Theta \cap G \neq \emptyset)$ for all open subsets $G \subseteq \mathfrak{Y}$. Then the *Choquet-Matheron theorem* states that the probability law of Θ is completely described by the simpler, albeit nonadditive, measure $c_{\Theta}(G)$.

The theory of random sets has evolved into a substantial subgenre of statistical theory (Molchanov 2005). For estimation theory, the concept of the *expected value* $\mathbb{E}[\Theta]$ of a random set Θ is of particular interest. Most definitions of $\mathbb{E}[\Theta]$ are very abstract (Molchanov 2005, Chap. 2). In certain circumstances, however, more conventional-looking definitions are possible. Suppose that $\mathfrak{Y}$ is a Euclidean space and that $\mathfrak{c}(2^{\mathfrak{Y}})$ is restricted to $\mathfrak{K}(2^{\mathfrak{Y}})$, the *bounded, convex, closed subsets* of $\mathfrak{Y}$. If C, C' are two such subsets, their *Minkowski sum* is $C + C' = \{c + c' \mid c \in C, c' \in C'\}$. Endowed with this definition of addition, $\mathfrak{K}(2^{\mathfrak{Y}})$ can be homeomorphically and homomorphically embedded into a certain space of functions (Molchanov 2005, pp. 199–200). Denote this embedding by $C \mapsto \phi_C$. Then the expected value $\mathbb{E}[\Theta]$ of Θ , defined in terms of Minkowski addition, corresponds to the *conventional* expected value $\mathbb{E}[\phi_{\Theta}]$ of the random function ϕ_{Θ} .

Random Finite Sets (Random Point Processes)

Suppose that the $\mathfrak{c}(2^{\mathfrak{Y}})$ is restricted to $\mathfrak{f}(2^{\mathfrak{Y}})$, the class of *finite* subsets of $\mathfrak{Y}$. (In many formulations, $\mathfrak{f}(2^{\mathfrak{Y}})$ is taken to be the class of *locally finite* subsets of $\mathfrak{Y}$ —i.e., those whose intersection

with compact subsets is finite.) A *random finite set* (RFS) is a measurable mapping from a probability space into $\mathfrak{f}(2^{\mathfrak{Y}})$. An example: the field of twinkling stars in some patch of a night sky. RFS theory is a particular mathematical formulation of *point process theory* (Daley and Vere-Jones 1998; Snyder and Miller 1991; Stoyan et al. 1995).

A *Poisson RFS* Ψ is perhaps the simplest nontrivial example of a random point pattern. It is specified by a *spatial distribution* $s(\mathbf{x})$ and an *intensity* μ . At any given instant, the probability that there will be n points in the pattern is $p(n) = e^{-\mu} \mu^n / n!$ (the value of the Poisson distribution). The probability that one of these n points will be $\mathbf{y}$ is $s(\mathbf{y})$. The function $D_{\Psi}(\mathbf{y}) = \mu \cdot s(\mathbf{y})$ is called the *intensity function* of Ψ .

At any moment, the point pattern produced by Ψ is a finite set $Y = \{\mathbf{y}_1, \dots, \mathbf{y}_n\}$ of points $\mathbf{y}_1, \dots, \mathbf{y}_n$ in $\mathfrak{Y}$, where $n = 0, 1, \dots$ and where $X = \emptyset$ if $n = 0$. If $n = 0$ then X represents the hypothesis that no objects at all are present. If $n = 1$ then $Y = \{\mathbf{y}_1\}$ represents the hypothesis that a single object $\mathbf{y}_1$ is present. If $n = 2$ then $Y = \{\mathbf{y}_1, \mathbf{y}_2\}$ represents the hypothesis that there are two distinct objects $\mathbf{y}_1 \neq \mathbf{y}_2$. And so on.

The *probability distribution* of Ψ —i.e., the probability that Ψ will have $Y = \{\mathbf{y}_1, \dots, \mathbf{y}_n\}$ as an instantiation—is entirely determined by its intensity function $D_{\Psi}(\mathbf{y})$:

$$\begin{aligned} f_{\Psi}(Y) &= f_{\Psi}(\{\mathbf{y}_1, \dots, \mathbf{y}_n\}) \\ &= \frac{e^{-\mu}}{n!} \cdot D_{\Psi}(\mathbf{y}_1) \cdots D_{\Psi}(\mathbf{y}_n) \end{aligned}$$

Every suitably well-behaved RFS Ψ has a probability distribution $f_{\Psi}(Y)$ and an intensity function $D_{\Psi}(\mathbf{y})$ (a.k.a. *first-moment density*). A Poisson RFS is unique in that $f_{\Psi}(Y)$ is completely determined by $D_{\Psi}(\mathbf{y})$.

Conventional signal processing is often concerned with single-object random systems that have the form

$$\mathbf{Z} = \eta(\mathbf{x}) + \mathbf{V}$$

where $\mathbf{x}$ is the state of the system; $\eta(\mathbf{x})$ is the “signal” generated by the system; the zero-mean random vector $\mathbf{V}$ is the random “noise” associated

the sensor; and $\mathbf{Z}$ is the random measurement that is observed. The purpose of signal processing is to construct an estimate $\hat{\mathbf{x}}(\mathbf{z}_1, \dots, \mathbf{z}_k)$ of $\mathbf{x}$, using the information contained in one or more draws $\mathbf{z}_1, \dots, \mathbf{z}_k$ from the random variable $\mathbf{Z}$.

RFS theory is analogously concerned with random systems that have the form

$$\Sigma = \Upsilon(X) \cup \Omega$$

where a random finite point pattern $\Upsilon(X)$ is the “signal” generated by the point pattern X (which is an instantiation of a random point pattern Ξ); Ω is a random finite point “noise” pattern; Σ is the total random finite point pattern that has been observed; and “ $\cup$ ” denotes set-theoretic union. One goal of RFS theory is to devise algorithms that can construct an estimate $\hat{X}(Z_1, \dots, Z_k)$ of X , using multiple point patterns $Z_1, \dots, Z_k \subseteq \mathfrak{Y}$ drawn from Σ . One approximate approach is that of estimating only the first-moment density $D_{\Xi}(\mathbf{x})$ of Ξ .

Stochastic Geometry

Stochastic geometry addresses more complicated random patterns. An example: the field of twinkling stars in a *quantized* patch of the night sky, in which case the measurement is the union $c_1 \cup \dots \cup c_n$ of a finite number of hexagonally shaped cells.

This is one instance of a *germ-grain process* (Stoyan et al. 1995, pp. 59–64). Such a process is specified by two items: an RFS Ψ and a function $c_{\mathbf{y}}$ that associates with each $\mathbf{y}$ in $\mathfrak{Y}$ a closed subset $c_{\mathbf{y}} \subseteq \mathfrak{Z}$. For example, if $\mathfrak{Y} = \mathbb{R}^2$ is the real-valued plane, then $c_{\mathbf{y}}$ could be the disk of radius r centered at $\mathbf{y} = (x, y)$. Let $Y = \{\mathbf{y}_1, \dots, \mathbf{y}_n\}$ be a particular random draw from Ψ . The points $\mathbf{y}_1, \dots, \mathbf{y}_n$ are the “germs,” and $c_{\mathbf{y}_1}, \dots, c_{\mathbf{y}_n}$ are the “grains” of this random draw from the germ-grain process Θ . The total pattern in $\mathfrak{Y}$ is the union $c_{\mathbf{y}_1} \cup \dots \cup c_{\mathbf{y}_n}$ of the grains—a random draw from Θ . Germ-grain processes can be used to model many kinds of natural processes. One example is the distribution of graphite particles in a two-dimensional section of a piece of iron, in which case the $c_{\mathbf{y}}$ could be chosen to be line segments rather than disks.

Stochastic geometry is concerned with random binary images that have observation structures such as

$$\Theta = (S \cap \Delta) \cup \Omega$$

where S is a “signal” pattern; Δ is a random pattern that models obscurations; Ω is a random pattern that models clutter; and Θ is the total pattern that has been observed. A common simplifying assumption is that Ω and Δ^c are germ-grain processes. One goal of stochastic geometry is to devise algorithms that can construct an optimal estimate $\hat{S}(T_1, \dots, T_k)$ of S , using multiple patterns $T_1, \dots, T_k \subseteq \mathfrak{Y}$ drawn from Θ .

Random Sets and Image Processing

Both point process theory and stochastic geometry have found extensive application to image-processing applications. These are considered briefly in turn.

Stochastic Geometry and Image Processing

Stochastic geometry methods are based on the use of a “structuring element” B (a geometrical shape, such as a disk, sphere, or more complex structure) to modify an image.

The *dilation* of a set S by B is $S \oplus B$ where “ $\oplus$ ” is Minkowski addition (Stoyan et al. 1995). Dilation tends to fill in cavities and fissures in images. The *erosion* of S is $S \ominus B = (S^c \oplus B^c)^c$ where “ c ” indicates set-theoretic complement. Erosion tends to create and increase the size of cavities and fissures. *Morphological filters* are constructed from various combinations of dilation and erosion operators.

Suppose that a binary image $\Sigma = S$ has been degraded by some measurement process—for example, the process $\Theta = (S \cap \Delta) \cup \Omega$. Then *image restoration* refers to the construction of an estimate $\hat{S}(T)$ of the original image S from a single degraded image $\Theta = T$. The restoration operator $\hat{S}(T)$ is *optimal* if it can be shown to be optimally close to S , given some concept of closeness. The *symmetric difference*

$$T_1 \sqcup T_2 = (T_1 \cup T_2) - (T_1 \cap T_2)$$

is a commonly used method for measuring the dissimilarity of binary images. It can be used to construct measures of distance between random images. One such distance is

$$d(\Theta_1, \Theta_2) = \mathbb{E}[|\Theta_1 \sqcup \Theta_2|]$$

where $|S|$ denotes the size of the set S and $\mathbb{E}[A]$ is the expected value of the random number A . Other distances require some definition of the expected value $\mathbb{E}[\Theta]$ of a random set Θ . It has been shown that, under certain circumstances, certain morphological operators can be viewed as consistent maximum a posteriori (MAP) estimators of S (Goutsias et al. 1997, p. 97).

RFS Theory and Image Processing Positron-emission tomography (PET) is one example of the application of RFS theory. In PET, tissues of interest are suffused with a positron-emitting radioactive isotope. When a positron annihilates an electron in a suitable fashion, two photons are emitted in opposite directions. These photons are detected by sensors in a ring surrounding the radiating tissue. The location of the annihilation on the line can be estimated by calculating time difference-of-arrival.

Because of the physics of radioactive decay, the annihilations can be accurately modeled as a Poisson RFS Ψ . Since a Poisson RFS is completely determined by its intensity function $D_\Psi(\mathbf{x})$, it is natural to try to estimate $D_\Psi(\mathbf{x})$. This yields the spatial distribution $s_\Psi(\mathbf{y})$ of annihilations—which, in turn, is the basis of the PET image (Snyder and Miller 1991, pp. 115–119).

Random Sets and Multitarget Processing

The purpose of this section is to summarize the application of RFS theory to multitarget detection, tracking, and localization. An example: tracking the positions of stars in the night sky over an extended period of time.

Suppose that there are an unknown number n of targets with unknown states $\mathbf{x}_1, \dots, \mathbf{x}_n$. The state of the entire multitarget system is a finite set $X = \{\mathbf{x}_1, \dots, \mathbf{x}_n\}$ with $n \geq 0$. When interrogating a scene, many sensors (such as radars) produce a measurement of the form $Z = \{\mathbf{z}_1, \dots, \mathbf{z}_m\}$ —i.e., a finite set of measurements. Some of these measurements are generated by background clutter Ω_k . Others are generated by the targets, with some targets possibly not having generated any. Mathematically speaking, Z is a random draw from an RFS Σ_k that can be decomposed as $\Sigma_k = \Upsilon(X_k) \cup \Omega_k$, where $\Upsilon(X_k)$ is the set of target-generated measurements.

Conventional Multitarget Detection and Tracking This is based on a “divide and conquer” strategy with three basic steps: *time-update*, *data association*, and *measurement-update*. At time t_k we have n “tracks” $\tau_1, \dots, \tau_n$ (hypothesized targets). In the time-update, an extended Kalman filter (EKF) is used to time-predict the tracks τ_i to *predicted tracks* τ_i^+ at the time t_{k+1} of the next measurement-set $Z_{k+1} = \{\mathbf{z}_1, \dots, \mathbf{z}_m\}$.

Given Z_{k+1} , we can construct the following *data-association hypothesis* H : for each $i = 1, \dots, n$, the predicted track τ_i^+ generated the detection $\mathbf{z}_{j_i}$ for some index j_i ; or, alternatively, this track was not detected at all. If we remove from Z_{k+1} all of the $\mathbf{z}_{j_1}, \dots, \mathbf{z}_{j_n}$, the remaining measurements are interpreted as being either clutter or as having been generated by new targets. Enumerating all possible association hypotheses (which is a combinatorially complex procedure), we end up with a “hypothesis table” $H_1, \dots, H_\nu$.

Given H_i , let $\mathbf{z}_{j_i}$ be the measurement that is hypothesized to have been generated by predicted track τ_i^+ . Then the measurement-update step of an EKF is used to construct a measurement-updated track τ_{i,j_i} from τ_i^+ and $\mathbf{z}_{j_i}$. Attached to each H_i is a *hypothesis probability* p_i —the probability that the particular hypothesis H_i is the correct one. The hypothesis with largest p_i yields the multitarget estimate $\hat{X} = \{\hat{\mathbf{x}}_1, \dots, \hat{\mathbf{x}}_{\hat{n}}\}$.

RFS Multitarget Detection and Tracking In the place of tracks and hypothesis tables, this uses

multitarget state-sets and *multitarget probability distributions*. In place of the conventional time-update, data association, and measurement-update, it uses a *recursive Bayes filter*. A random multitarget state-set is an RFS $\Xi_{k|k}$ whose points are target states. A multitarget probability distribution is the probability distribution $f(X_k|Z_{1:k}) = f_{\Xi_{k|k}}(X)$ of the RFS $\Xi_{k|k}$, where $Z_{1:k} : Z_1, \dots, Z_k$ is the time-sequence of measurement-sets at time t_k .

RFS Time-Update The Bayes filter time-update step $f(X_k|Z_{1:k}) \rightarrow f(X_{k+1}|Z_{1:k})$ requires a *multitarget Markov transition function* $f(X_{k+1}|X_k)$. It is the probability that the multitarget system will have multitarget state-set X_{k+1} at time t_{k+1} , if it had multitarget state-set X_k at time t_k . It takes into account all pertinent characteristics of the targets: individual target motion, target appearance, target disappearance, environmental constraints, etc. It is explicitly constructed from an *RFS multitarget motion model* using a *multitarget integro-differential calculus*.

RFS Measurement-Update The Bayes filter measurement-update step $f(X_{k+1}|Z_{1:k}) \rightarrow f(X_{k+1}|Z_{1:k+1})$ is just Bayes’ rule. It requires a *multitarget likelihood function* $f(Z_{k+1}|X_{k+1})$ —the likelihood that a measurement-set Z will be generated, if a system of targets with state-set X is present. It takes into account all pertinent characteristics of the sensor(s): sensor noise, fields of view and obscurations, probabilities of detection, false alarms, and/or clutter. It is explicitly constructed from an *RFS measurement model* using multitarget calculus.

RFS State-Estimation Determination of the number n and states $\mathbf{x}_1, \dots, \mathbf{x}_n$ of the targets is accomplished using a *Bayes-optimal multitarget state estimator*. The idea is to determine the X_{k+1} that maximizes $f(X_{k+1}|Z_{1:k+1})$ in some sense.

Approximate Multitarget RFS Filters The multitarget Bayes filter is, in general, computationally intractable. Central to the RFS approach is a toolbox of techniques—including

the multitarget calculus—designed to produce *statistically principled* approximate multitarget filters. The two most well-studied are the *probability hypothesis density* (PHD) filter and its generalization, the *cardinalized PHD* (CPHD) filter. In such filters, $f(X_k|Z_{1:k})$ is replaced by the first-moment density $D(\mathbf{x}_k|Z_{1:k})$ of $\Xi_{k|k}$. These filters have been shown to be faster and perform as well as or better than conventional approaches in some applications.

Labeled RFSs and RFS Trackers In order to maintain connected target trajectories through time, the PHD and CPHD filters use heuristic rules to attach unique identifiers (“track labels”) to targets. The *labeled RFS theory* of Vo and Vo (2013) provides a theoretically rigorous approach to track labeling. In this theory, target states have the form $\mathbf{x} = (\mathbf{u}, \ell)$ where $\mathbf{u}$ is the kinematic state and ℓ is a uniquely identifying unknown target label. The *labeled* multitarget Bayes filter propagates the distribution $f(X_k|Z_{1:k}) = f_{\Xi_{k|k}}(X)$ of the LRFS $\Xi_{k|k}$. When Bayes-optimal multitarget state estimates $\hat{X}_k$ are extracted from the $f(X_k|Z_{1:k})$, the target trajectory with label ℓ consists of those $(\mathbf{u}_k, \ell)$ with $k \geq 1$ for which $(\mathbf{u}_k, \ell) \in \hat{X}_k$.

The Generalized Labeled Multi-Bernoulli (GLMB) Filter The Kalman filter is an exact closed-form solution of the single-target recursive Bayes filter. That is: suppose that the single-target Markov transition functions $f(\mathbf{x}_{k+1}|\mathbf{x}_k)$, single-target likelihood functions $f(\mathbf{z}_{k+1}|\mathbf{x}_{k+1})$, and single-target initial distribution $f(\mathbf{x}_0)$ are linear Gaussian. Then $f(\mathbf{x}_k|\mathbf{z}_{1:k-1}) = N_{P_{k|k-1}}(\mathbf{x}_k - \mathbf{x}_{k|k-1})$ and $f(\mathbf{x}_k|\mathbf{z}_{1:k}) = N_{P_{k|k}}(\mathbf{x}_k - \mathbf{x}_{k|k})$ for $k \geq 1$, where $(\mathbf{x}_{k|k}, P_{k|k})$, $(\mathbf{x}_{k|k-1}, P_{k|k-1})$ are the Kalman filter’s states and covariance matrices.

Vo and Vo (2013) demonstrated that this reasoning generalizes to multitarget tracking. Let $f(X_{k+1}|X_k)$ be the transition density for the “standard” multitarget motion model and $f(Z_{k+1}|X_{k+1})$ the likelihood function for the “standard” multitarget measurement model. Then the labeled multitarget Bayes filter is algebraically closed with respect to the

parametrized family of “GLMB distributions.” The GLMB filter results when GLMB parameters are propagated instead of GLMB distributions. It can be tractably implemented using Gibbs sampling techniques (Vo et al. 2017) and can simultaneously track over a million targets in two dimensions in significant clutter, using off-the-shelf computing equipment (Beard et al. 2018).

Random Sets and Human-Mediated Data

Natural-language statements and inference rules have already been mentioned as examples of human-mediated information. *Expert-systems theory* was introduced in part to address situations—such as this—that involve uncertainties other than randomness. Expert-system methodologies include *fuzzy set theory*, the *Dempster-Shafer* (D-S) *theory of uncertain evidence*, and *rule-based inference*. RS theory provides solid Bayesian foundations for them and allows human-mediated data to be processed using standard Bayesian estimation techniques. The purpose of this section is to briefly summarize this aspect of the RS approach.

The relationships between expert-systems theory and random set theory were first established by researchers such as Orlov (1978), Höhle (1981), Nguyen (1978), and Goodman and Nguyen (1985). At a relatively early stage, it was recognized that random set theory provided a potential means of unifying much of expert-systems theory (Goodman and Nguyen 1985; Kruse et al. 1991).

A conventional sensor measurement at time t_k is typically represented as $\mathbf{Z}_k = \eta(\mathbf{x}_k) + \mathbf{V}_k$ —equivalently formulated as a *likelihood function* $f(\mathbf{z}_k|\mathbf{x}_k)$. It is conventional to think of $\mathbf{z}_k$ as the actual “measurement” and of $f(\mathbf{z}_k|\mathbf{x}_k)$ as the full description of the uncertainty associated with it. In actuality, $\mathbf{z}$ is just a *mathematical model* $\mathbf{z}_{\zeta_k}$ of some *real-world measurement* ζ_k . Thus the likelihood actually has the form $f(\zeta_k|\mathbf{x}_k) = f(\mathbf{z}_{\zeta_k}|\mathbf{x}_k)$.

This observation assumes crucial importance when one considers human-mediated data. Consider the simple natural-language statement

$\zeta = \text{“The target is near the tower”}$

where the *tower* is a landmark, located at a known position (x_0, y_0) , and where the term “near” is assumed to have the following specific meaning: (x, y) is near (x_0, y_0) means that $(x, y) \in T_5$ where T_5 is a disk of radius 5 m, centered at (x_0, y_0) . If $\mathbf{z} = (x, y)$ is the actual measurement of the target’s position, then ζ is *equivalent to the formula* $\mathbf{z} \in T_5$. Since $\mathbf{z}$ is just one possible draw from $\mathbf{Z}_k$, we can say that ζ —or equivalently, T_5 —is actually a constraint on the underlying measurement process: $\mathbf{Z}_k \in T_5$.

Because the word “near” is rather vague, we could just as well say that $\mathbf{z} \in T_5$ is the best choice, with confidence $w_5 = 0.7$; that $\mathbf{z} \in T_4$ is the next-best choice, with confidence $w_4 = 0.2$; and that $\mathbf{z} \in T_6$ is the least best, with confidence $w_6 = 0.1$. Let Θ be the random subset of $\mathcal{Z}$ defined by $\Pr(\Theta = T_i) = w_i$ for $i = 4, 5, 6$. In this case, ζ is equivalent to the *random constraint*

$$\mathbf{Z}_k \in \Theta$$

The probability

$$\begin{aligned}\rho_k(\Theta|\mathbf{x}) &= \Pr(\eta(\mathbf{x}_k) + \mathbf{V}_k \in \Theta) \\ &= \Pr(\mathbf{Z} \in \Theta | \mathbf{X} = \mathbf{x})\end{aligned}$$

is called a *generalized likelihood function* (GLF). GLFs can be constructed for more complex natural-language statements, for inference rules, and more. Using their GLF representations, such “nontraditional measurements” can be processed using single- and multi-object recursive Bayes filters and their approximations. As a consequence, it can be shown that fuzzy-logic, the D-S theory, and rule-based inference can be subsumed within a single Bayesian-probabilistic paradigm.

Summary and Future Directions

In the engineering world, the theory of random sets has been associated primarily with certain specialized image processing applications, such as morphological filters and tomographic

imaging. It has more recently found application in fields such as multitarget tracking and in expert-systems theory. All of these fields of application remain areas of active research.

Recommended Reading

Molchanov (2005) provides a definitive exposition of the general theory of random sets. Two excellent references for stochastic geometry are Stoyan et al. (1995) and Barndorff-Nielsen and Lieshout (1999). The books by Kingman (1993) and by Daley and Vere-Jones (1998) are good introductions to point process theory. The application of point process theory and stochastic geometry to image-processing is addressed in, respectively, Snyder and Miller (1991) and Stoyan et al. (1995). The application of RFSs to multitarget estimation is addressed in the tutorials Mahler (2013, 2014) and the books Mahler (2007, 2014). Introductions to the application of random sets to expert systems can be found in Kruse et al. (1991), Mahler (2007), Chaps. 3–6, and Mahler (2014) (Chap. 22).

Abstract

This entry discusses the history and describes the multitude of methods and applications of

this important branch of stochastic process theory.

Keywords

Linear stochastic filtering · Markov step processes · Maximum likelihood estimation · Riccati equation · Stratonovich-Kushner equation

Estimation is the process of inferring the value of an unknown given quantity of interest from noisy, direct or indirect, observations of such a quantity. Due to its great practical relevance, estimation has a long history and an enormous variety of applications in all fields of engineering and science. A certainly incomplete list of possible application domains of estimation includes the following: statistics (Lehmann and Casella 1998; Bard 1974; Wertz 1978; Ghosh et al. 1997; Koch 1999; Tsybakov 2009), telecommunication systems (Snyder 1968; Van Trees 1971; Sage and Melsa 1971; Schonhoff and Giordano 2006), signal and image processing (Kay 1993; Itakura 1971; Wakita 1973; Poor 1994; Elliott et al. 2008; Barkat 2005; Levy 2008; Najim 2008; Tuncer and Friedlander 2009; Woods and Radewan 1977; Biemond et al. 1983; Kim and Woods 1998), aerospace engineering (McGee and Schmidt 1985), tracking (Farina and Studer 1985, 1986; Blackman and Popoli 1999; Bar-Shalom et al. 2001, 2013; Bar-Shalom and Fortmann 1988), navigation (Schmidt 1966; Farrell and Barth 1999; Grewal et al. 2001; Smith et al. 1986; Dissanayake et al. 2001; Durrant-Whyte and Bailey 2006a,b; Thrun et al. 2006; Mullane et al. 2011), control systems (Kalman 1960a; Joseph and Tou 1961; Athans 1971; Anderson and Moore 1979; Maybeck 1979, 1982; Stengel 1994; Söderström 1994; Goodwin et al. 2005), econometrics (Zellner 1971; Pindyck and Roberts 1974; Aoki 1987), geophysics (e.g., seismic deconvolution) (Flinn et al. 1967; Bayless and Brigham 1970; Mendel 1977, 1983, 1990), oceanography (Ghil and Malanotte-Rizzoli 1991; Evensen 1994a), weather forecasting (McGarty

1971; Evensen 1994b, 2007), environmental engineering (Nachazel 1993; Dochain and Vanrolleghem 2001; Heemink and Segers 2002), demographic systems (Leibungudt et al. 1983), automotive systems (Stephant et al. 2004; Barbarisi et al. 2006), failure detection (Willsky 1976; Mangoubi 1998; Chen and Patton 1999), power systems (Debs and Larson 1970; Toyoda et al. 1970; Miller and Lewis 1971; Monticelli 1999; Abur and Gómez Espósito 2004), nuclear engineering (Sage and Masters 1967; Roman et al. 1971; Venerus and Bullock 1970; Robinson 1963), biomedical engineering (Stark 1968; Snyder 1970; Bekey 1973), pattern recognition (Ho and Agrawala 1968; Lainiotis 1972; Andrews 1972), social networks (Snijders et al. 2012), etc.

Chapter Organization

The rest of the chapter is organized as follows. Section “[Historical Overview on Estimation](#)” will provide a historical overview on estimation. The next section will discuss applications of estimation. Connections between estimation and information theories will be explored in the subsequent section. Finally, the section “[Conclusions and Future Trends](#)” will conclude the chapter by discussing future trends in estimation. An extensive list of references is also provided.

Historical Overview on Estimation

A possibly incomplete, list of the major achievements on estimation theory and applications is reported in Table 1. The entries of the table, sorted in chronological order, provide for each contribution the name of the inventor (or inventors), the date, and a short description with main bibliographical references.

Probably the first important application of estimation dates back to the beginning of the nineteenth century whenever least-squares estimation (LSE), invented by Gauss in 1795 (Gauss 1995; Legendre 1810), was successfully exploited in astronomy for predicting planet

orbits (Gauss 1806). Least-squares estimation follows a deterministic approach by minimizing the sum of squares of residuals defined as differences between observed data and model-predicted estimates. A subsequently introduced statistical approach is maximum likelihood estimation (MLE), popularized by R. A. Fisher between 1912 and 1922 (Fisher 1912, 1922, 1925). MLE consists of finding the estimate of the unknown quantity of interest as the value that maximizes the so-called likelihood function, defined as the conditional probability density function of the observed data given the quantity to be estimated. In intuitive terms, MLE maximizes the agreement of the estimate with the observed data. Whenever the observation noise is assumed Gaussian (Kim and Shevlyakov 2008; Park et al. 2013), MLE coincides with LSE.

While estimation problems had been addressed for several centuries, it was not until the 1940s that a systematic theory of estimation started to be established, mainly relying on the foundations of the modern theory of probability (Kolmogorov 1933). Actually, the roots of probability theory can be traced back to the calculus of combinatorics (the Stomachion puzzle invented by Archimedes (Netz and Noel 2011)) in the third century B.C. and to the gambling theory (work of Cardano, Pascal, de Fermat, Huygens) in the sixteenth–seventeenth centuries.

Differently from the previous work devoted to the estimation of constant parameters, in the period 1940–1960 the attention was mainly shifted toward the estimation of signals. In particular, Wiener in 1940 (Wiener 1949) and Kolmogorov in 1941 (Kolmogorov 1941) formulated and solved the problem of linear minimum mean-square error (MMSE) estimation of continuous-time and, respectively, discrete-time stationary random signals. In the late 1940s and in the 1950s, Wiener-Kolmogorov’s theory was extended and generalized in many directions exploiting both time-domain and frequency-domain approaches. At the beginning of the 1960s Rudolf E. Kálmán made pioneering contributions to estimation by providing the mathematical foundations of the modern theory

Estimation, Survey on, Table 1 Major developments on estimation

Archimedes	Third century B.C.	Combinatorics (Netz and Noel 2011) as the basis of probability
G. Cardano, B. Pascal, P. de Fermat, C. Huygens	Sixteenth–seventeenth centuries	Roots of the theory of probability (Devlin 2008)
J. F. Riccati	1722–1723	Differential Riccati equation (Riccati 1722, 1723), subsequently exploited in the theory of linear stochastic filtering
T. Bayes	1763	Bayes' formula on conditional probability (Bayes 1763; McGrayne 2011)
C. F. Gauss, A. M. Legendre	1795–1810	Least-squares estimation and its applications to the prediction of planet orbits (Gauss 1806, 1995; Legendre 1810)
P. S. Laplace	1814	Theory of probability (Laplace 1814)
R. A. Fisher	1912–1922	Maximum likelihood estimation (Fisher 1912, 1922, 1925)
A. N. Kolmogorov	1933	Modern theory of probability (Kolmogorov 1933)
N. Wiener	1940	Minimum mean-square error estimation of continuous-time stationary random signals (Wiener 1949)
A. N. Kolmogorov	1941	Minimum mean-square error estimation of discrete-time stationary random signals (Kolmogorov 1941)
H. Cramér, C. R. Rao	1945	Theoretical lower bound on the covariance of estimators (Rao 1945; Cramér 1946)
S. Ulam, J. von Neumann, N. Metropolis, E. Fermi	1946–1949	Monte Carlo method (Ulam et al. 1947; Metropolis and Ulam 1949; Ulam 1952; Los Alamos Scientific Laboratory 1966)
J. Sklansky, T. R. Benedict, G. W. Bordner, H. R. Simpson, S. R. Neal	1957–1967	$\alpha - \beta$ and $\alpha - \beta - \gamma$ filters (Sklansky 1957; Benedict and Bordner 1962; Simpson 1963; Neal 1967; Painter et al. 1990)
R. L. Stratonovich, H. J. Kushner	1959–1964	Bayesian approach to stochastic nonlinear filtering of continuous-time systems, i.e., Stratonovich-Kushner equation for the evolution of the state conditional probability density (Stratonovich 1959, 1960; Kushner 1962, 1967; Jazwinski 1970)
R. E. Kalman	1960	Linear filtering and prediction for discrete-time systems (Kalman 1960b)
R. E. Kalman	1961	Observability of linear dynamical systems (Kalman 1960a)
R. E. Kalman, R. S. Bucy	1961	Linear filtering and prediction for continuous-time systems (Kalman and Bucy 1961)
A. E. Bryson, M. Frazier, H. E. Rauch, F. Tung, C. T. Striebel, D. Q. Mayne, J. S. Meditch, D. C. Fraser, L. E. Zachrisson, B. D. O. Anderson, etc.	Since 1963	Smoothing of linear and nonlinear systems (Bryson and Frazier 1963; Rauch 1963; Rauch et al. 1965; Mayne 1966; Meditch 1967; Zachrisson 1969; Anderson and Chirarattananon 1972)
D. G. Luenberger	1964	State observer for a linear system (Luenberger 1964)
Y. C. Ho, R. C. K. Lee	1964	Bayesian approach to recursive nonlinear estimation for discrete-time systems (Ho and Lee 1964)
W. M. Wonham	1965	Optimal filtering for Markov step processes (Wonham 1965)
A. H. Jazwinski	1966	Bayesian approach to stochastic nonlinear filtering for continuous-time stochastic systems with discrete-time observations (Jazwinski 1966)

M. Hernandez, A. Farina, B. 2006 Ristic		PCRLB for tracking in the case of detection probability less than one and false alarm probability greater than zero (Hernandez et al. 2006)
Olfati-Saber and others	Since 2007	Consensus filters (Olfati-Saber et al. 2007; Calafiore and Abrate 2009; Xiao et al. 2005; Alriksson and Rantzer 2006; Olfati-Saber 2007; Kamgarpour and Tomlin 2007; Stankovic et al. 2009; Battistelli et al. 2011, 2012, 2013; Battistelli and Chisci 2014) for networked estimation

based on state-variable representations. In particular, Kálmán solved the linear MMSE filtering and prediction problems both in discrete-time (Kalman 1960b) and in continuous-time (Kalman and Bucy 1961); the resulting optimal estimator was named after him, Kalman filter (KF). As a further contribution, Kalman also singled out the key technical conditions, i.e., observability and controllability, for which the resulting optimal estimator turns out to be stable. Kalman's work went well beyond earlier contributions of A. Kolmogorov, N. Wiener, and their followers ("frequency-domain" approach) by means of a general state-space approach. From the theoretical viewpoint, the KF is an optimal

estimator, in a wide sense, of the state of a linear dynamical system from noisy measurements; specifically it is the optimal MMSE estimator in the Gaussian case (e.g., for normally distributed noises and initial state) and the best linear unbiased estimator irrespective of the noise and initial state distributions. From the practical viewpoint, the KF enjoys the desirable properties of being linear and acting recursively, step-by-step, on a noise-contaminated data stream. This allows for cheap real-time implementation on digital computers. Further, the universality of "state-variable representations" allows almost any estimation problem to be included in the KF framework. For these reasons, the KF is,

and continues to be, an extremely effective and easy-to-implement tool for a great variety of practical tasks, e.g., to detect signals in noise or to estimate unmeasurable quantities from accessible observables. Due to the generality of the state estimation problem, which actually encompasses parameter and signal estimation as special cases, the literature on estimation since 1960 till today has been mostly concentrated on extensions and generalizations of Kalman's work in several directions. Considerable efforts, motivated by the ubiquitous presence of nonlinearities in practical estimation problems, have been devoted to nonlinear and/or non-Gaussian filtering, starting from the seminal papers of Stratonovich (1959, 1960) and Kushner (1962, 1967) for continuous-time systems, Ho and Lee (1964) for discrete-time systems, and Jazwinski (1966) for continuous-time systems with discrete-time observations. In these papers, state estimation is cast in a probabilistic (Bayesian) framework as the problem of evolving in time the state conditional probability density given observations (Jazwinski 1970). Work on nonlinear filtering has produced over the years several nonlinear state estimation algorithms, e.g., the extended Kalman filter (EKF) (Schmidt 1966), the unscented Kalman filter (UKF) (Julier et al. 1995; Julier and Uhlmann 2004), the Gaussian-sum filter (Sorenson and Alspach 1970, 1971; Alspach and Sorenson 1972), the sequential Monte Carlo (also called particle) filter (SMCF) (Gordon et al. 1993; Doucet et al. 2001; Ristic et al. 2004), and the ensemble Kalman filter (EnKF) (Evensen 1994a, b, 2007) which have been, and are still now, successfully employed in various application domains. In particular, the SMCF and EnKF are stochastic simulation algorithms taking inspiration from the work in the 1940s on the Monte Carlo method (Metropolis and Ulam 1949) which has recently got renewed interest thanks to the tremendous advances in computing technology. A thorough review on nonlinear filtering can be found, e.g., in Daum (2005) and Crisan and Rozovskii (2011).

Other interesting areas of investigation have concerned smoothing (Bryson and Frazier 1963), robust filtering for systems subject to

modeling uncertainties (Poor and Looze 1981), and state estimation for infinite-dimensional (i.e., distributed parameter and/or delay) systems (Balakrishnan and Lions 1967). Further, a lot of attention has been devoted to the implementation of the KF, specifically square-root filtering (Potter and Stern 1963) for improved numerical robustness and fast KF algorithms (Kailath 1973; Morf et al. 1974) for enhancing computational efficiency. Worth of mention is the work over the years on theoretical bounds on the estimation performance originated from the seminal papers of Rao (1945) and Cramér (1946) on the lower bound of the MSE for parameter estimation and subsequently extended in Tichavsky et al. (1998) to nonlinear filtering and in Hernandez et al. (2006) to more realistic estimation problems with possible missed and/or false measurements. An extensive review of this work on Bayesian bounds for estimation, nonlinear filtering, and tracking can be found in van Trees and Bell (2007). A brief review of the earlier (until 1974) state of art in estimation can be found in Lainiotis (1974).

Applications

Astronomy

The problem of making estimates and predictions on the basis of noisy observations originally attracted the attention many centuries ago in the field of astronomy. In particular, the first attempt to provide an optimal estimate, i.e., such that a certain measure of the estimation error be minimized, was due to Galileo Galilei that, in his *Dialogue on the Two World Chief Systems* (1632) (Galilei 1632), suggested, as a possible criterion for estimating the position of Tycho Brahe's supernova, the estimate that required the "minimum amendments and smallest corrections" to the data. Later, C. F. Gauss mathematically specified this criterion by introducing in 1795 the least-squares method (Gauss 1806, 1995; Legendre 1810) which was successfully applied in 1801 to predict the location of the asteroid Ceres. This asteroid, originally discovered by the Italian astronomer Giuseppe Piazzi on January 1, 1801, and then

lost in the glare of the sun, was in fact recovered 1 year later by the Hungarian astronomer F. X. von Zach exploiting the least-squares predictions of Ceres' position provided by Gauss.

Statistics

Starting from the work of Fisher in the 1920s (Fisher 1912, 1922, 1925), maximum likelihood estimation has been extensively employed in statistics for estimating the parameters of statistical models (Lehmann and Casella 1998; Bard 1974; Wertz 1978; Ghosh et al. 1997; Koch 1999; Tsybakov 2009).

Telecommunications and Signal/Image Processing

Wiener-Kolmogorov's theory on signal estimation, developed in the period 1940–1960 and originally conceived by Wiener during the Second World War for predicting aircraft trajectories in order to direct the antiaircraft fire, subsequently originated many applications in telecommunications and signal/image processing (Van Trees 1971; Kay 1993; Itakura 1971; Wakita 1973; Poor 1994; Elliott et al. 2008; Barkat 2005; Levy 2008; Najim 2008; Tuncer and Friedlander 2009; Woods and Radewan 1977; Biemond et al. 1983; Kim and Woods 1998). For instance, Wiener filters have been successfully applied to linear prediction, acoustic echo cancellation, signal restoration, and image/video de-noising. But it was the discovery of the Kalman filter in 1960 that revolutionized estimation by providing an effective and powerful tool for the solution of any, static or dynamic, stationary or adaptive, linear estimation problem. A recently conducted, and probably non-exhaustive, search has detected the presence of over 16,000 patents related to the “Kalman filter,” spreading over all areas of engineering and over a period of more than 50 years. What is astonishing is that even nowadays, more than 50 years after its discovery, one can see the continuous appearance of lots of new patents and scientific papers presenting novel applications and/or novel extensions in many directions (e.g., to nonlinear filtering) of the KF. Since 1992 the number of patents registered every year and related to the KF follows an exponential law.

Space Navigation and Aerospace Applications

The first important application of the Kalman filter was in the NASA (*National Aeronautic and Space Administration*) space program. As reported in a NASA technical report (McGee and Schmidt 1985), Kalman presented his new ideas while visiting Stanley F. Schmidt at the NASA Ames Research Center in 1960, and this meeting stimulated the use of the KF during the Apollo program (in particular, in the guidance system of Saturn V during Apollo 11 flight to the Moon), and, furthermore, in the NASA Space Shuttle and in Navy submarines and unmanned aerospace vehicles and weapons, such as cruise missiles. Further, to cope with the nonlinearity of the space navigation problem and the small word length of the onboard computer, the extended Kalman filter for nonlinear systems and square-root filter implementations for enhanced numerical robustness have been developed as part of the NASA's Apollo program. The aerospace field was only the first of a long and continuously expanding list of application domains where the Kalman filter and its nonlinear generalizations have found widespread and beneficial use.

Control Systems and System Identification

The work on Kalman filtering (Kalman 1960b; Kalman and Bucy 1961) had also a significant impact on control system design and implementation. In Kalman (1960a) duality between estimation and control was pointed out, in that for a certain class of control and estimation problems one can solve the control (estimation) problem for a given dynamical system by resorting to a corresponding estimation (control) problem for a suitably defined dual system. In particular, the Kalman filter has been shown to be dual of the linear-quadratic (LQ) regulator, and the two dual techniques constitute the linear-quadratic-Gaussian (LQG) (Joseph and Tou 1961) regulator. The latter consists of an LQ regulator feeding back in a linear way the state estimate provided by a Kalman filter, which can be independently designed in view of the separation principle. The KF as well as LSE and MLE techniques are also widely used in system identification

(Ljung 1999; Söderström and Stoica 1989) for both parameter estimation and output prediction purposes.

Tracking

One of the major application areas for estimation is tracking (Farina and Studer 1985, 1986; Blackman and Popoli 1999; Bar-Shalom et al. 2001, 2013; Bar-Shalom and Fortmann 1988), i.e., the task of following the motion of moving objects (e.g., aircrafts, ships, ground vehicles, persons, animals) given noisy measurements of kinematic variables from remote sensors (e.g., radar, sonar, video cameras, wireless sensors, etc.). The development of the Wiener filter in the 1940s was actually motivated by radar tracking of aircraft for automatic control of antiaircraft guns. Such filters began to be used in the 1950s whenever computers were integrated with radar systems, and then in the 1960s more advanced and better performing Kalman filters came into use. Still today it can be said that the Kalman filter and its nonlinear generalizations (e.g., EKF (Schmidt 1966), UKF (Julier and Uhlmann 2004), and particle filter (Gordon et al. 1993)) represent the workhorses of tracking and sensor fusion. Tracking, however, is usually much more complicated than a simple state estimation problem due to the presence of false measurements (clutter) and multiple objects in the surveillance region of interest, as well as for the uncertainty about the origin of measurements. This requires to use, besides filtering algorithms, smart techniques for object detection as well as for association between detected objects and measurements. The problem of joint target tracking and classification has also been formulated as a hybrid state estimation problem and addressed in a number of papers (see, e.g., Smeth and Ristic (2004) and the references therein).

Econometrics

State and parameter estimation have been widely used in econometrics (Aoki 1987) for analyzing and/or predicting financial time series (e.g., stock prices, interest rates, unemployment rates, volatility etc.).

Geophysics

Wiener and Kalman filtering techniques are employed in reflection seismology for estimating the unknown earth reflectivity function given noisy measurements of the seismic wavelet's echoes recorded by a geophone. This estimation problem, known as seismic deconvolution (Mendel 1977, 1983, 1990), has been successfully exploited, e.g., for oil exploration.

Data Assimilation for Weather Forecasting and Oceanography

Another interesting application of estimation theory is data assimilation (Ghil and Malanotte-Rizzoli 1991) which consists of incorporating noisy observations into a computer simulation model of a real system. Data assimilation has widespread use especially in weather forecasting and oceanography. A large-scale state-space model is typically obtained from the physical system model, expressed in terms of partial differential equations (PDEs), by means of a suitable spatial discretization technique so that data assimilation is cast into a state estimation problem. To deal with the huge dimensionality of the resulting state vector, appropriate filtering techniques with reduced computational load have been suitably developed (Evensen 2007).

Global Navigation Satellite Systems

Global Navigation Satellite Systems (GNSSs), such as GPS put into service in 1993 by the US Department of Defense, provide nowadays a commercially diffused technology exploited by millions of users all over the world for navigation purposes, wherein the Kalman filter plays a key role (Bar-Shalom et al. 2001). In fact, the Kalman filter not only is employed in the core of the GNSS to estimate the trajectories of all the satellites, the drifts and rates of all system clocks, and hundreds of parameters related to atmospheric propagation delay, but also any GNSS receiver uses a nonlinear Kalman filter, e.g., EKF, in order to estimate its own position and velocity along with the bias and drift of its own clock with respect to the GNSS time.

Robotic Navigation (SLAM)

Recursive state estimation is commonly employed in mobile robotics (Thrun et al. 2006) in order to on-line estimate the robot pose, location and velocity, and, sometimes, also the location and features of the surrounding objects in the environment exploiting measurements provided by onboard sensors; the overall joint estimation problem is referred to as SLAM (simultaneous localization and mapping) (Smith et al. 1986; Dissanayake et al. 2001; Durrant-Whyte and Bailey 2006a, b; Thrun et al. 2006; Mullane et al. 2011).

Automotive Systems

Several automotive applications of the Kalman filter, or of its nonlinear variants, are reported in the literature for the estimation of various quantities of interest that cannot be directly measured, e.g., roll angle, sideslip angle, road-tire forces, heading direction, vehicle mass, state of charge of the battery (Barbarisi et al. 2006), etc. In general, one of the major applications of state estimation is the development of virtual sensors, i.e., estimation algorithms for physical variables of interest, that cannot be directly measured for technical and/or economic reasons (Stephant et al. 2004).

Miscellaneous Applications

Other areas where estimation has found numerous applications include electric power systems (Debs and Larson 1970; Toyoda et al. 1970; Miller and Lewis 1971; Monticelli 1999; Abur and Gómez Espósito 2004), nuclear reactors (Sage and Masters 1967; Roman et al. 1971; Venerus and Bullock 1970; Robinson 1963), biomedical engineering (Stark 1968; Snyder 1970; Bekey 1973), pattern recognition (Ho and Agrawala 1968; Lainiotis 1972; Andrews 1972), and many others.

Connection Between Information and Estimation Theories

In this section, the link between two fundamental quantities in information theory and estimation

theory, i.e., the mutual information (MI) and respectively the minimum mean-square error (MMSE), is investigated. In particular, a strikingly simple but very general relationship can be established between the MI of the input and the output of an additive Gaussian channel and the MMSE in estimating the input given the output, regardless of the input distribution (Guo et al. 2005). Although this functional relation holds for general settings of the Gaussian channel (e.g., both discrete-time and continuous-time, possibly vector, channels), in order to avoid the heavy mathematical preliminaries needed to treat rigorously the general problem, two simple scalar cases, a static and a (continuous-time) dynamic one, will be discussed just to highlight the main concept.

Static Scalar Case

Consider two scalar real-valued random variables, x and y , related by

$$y = \sqrt{\sigma}x + v \quad (1)$$

where v , the measurement noise, is a standard Gaussian random variable independent of x and σ can be regarded as the gain in the output signal-to-noise ratio (SNR) due to the channel. By considering the MI between x and y as a function of σ , i.e., $I(\sigma) = I(x, \sqrt{\sigma}x + v)$, it can be shown that the following relation holds (Guo et al. 2005):

$$\frac{d}{d\sigma} I(\sigma) = \frac{1}{2} E \left[(x - \hat{x}(\sigma))^2 \right] \quad (2)$$

where $\hat{x}(\sigma) = E[x|\sqrt{\sigma}x + v]$ is the minimum mean-square error estimate of x given y . Figure 1 displays the behavior of both MI, in natural logarithmic units of information (nats), and MMSE versus SNR.

As mentioned in Guo et al. (2005), the above information-estimation relationship (2) has found a number of applications, e.g., in nonlinear filtering, in multiuser detection, in power allocation over parallel Gaussian channels, in the proof of Shannon's entropy power inequality and its

Estimation, Survey on,
Fig. 1 MI and MMSE
versus SNR

generalizations, as well as in the treatment of the capacity region of several multiuser channels.

1970; Mayer-Wolf and Zakai 1983)

Linear Dynamic Continuous-Time Case

While in the static case the MI is assumed to be a function of the SNR, in the dynamic case it is of great interest to investigate the relationship between the MI and the MMSE as a function of time.

Consider the following first-order (scalar) linear Gaussian continuous-time stochastic dynamical system:

$$\begin{aligned} dx_t &= ax_t dt + dw_t \\ dy_t &= \sqrt{\sigma} x_t dt + dv_t \end{aligned} \quad (3)$$

where a is a real-valued constant while w_t and v_t are independent standard Brownian motion processes that represent the process and, respectively, measurement noises. Defining by $x_0^t \triangleq \{x_s, 0 \leq s \leq t\}$ the collection of all states up to time t and analogously $y_0^t \triangleq \{y_s, 0 \leq s \leq t\}$ for the channel outputs (i.e., measurements) and considering the MI between x_0^t and y_0^t as a function of time t , i.e., $I(t) = I(x_0^t, y_0^t)$, it can be shown that (Duncan

$$\frac{d}{dt} I(t) = \frac{\sigma}{2} E \left[(x_t - \hat{x}_t)^2 \right] \quad (4)$$

where $\hat{x}_t = E[x_t | y_0^t]$ is the minimum mean-square error estimate of the state x_t given all the channel outputs up to time t , i.e., y_0^t . Figure 2 depicts the time behavior of both MI and MMSE for several values of σ and $a = 1$.

Conclusions and Future Trends

Despite the long history of estimation and the huge amount of work on several theoretical and practical aspects of estimation, there is still a lot of research investigation to be done in several directions. Among the many new future trends, networked estimation and quantum estimation (briefly overviewed in the subsequent parts of this section) certainly deserve special attention due to the growing interest on wireless sensor networks and, respectively, quantum computing.

Networked Information Fusion and Estimation

Information or data fusion is about combining, or fusing, information or data from multiple sources to provide knowledge that is not evident from a single source (Farina and Studer 1986; Bar-Shalom et al. 2013). In 1986, an effort to standardize the terminology related to data fusion began and the JDL (Joint Directors of Laboratories) data fusion working group was established. The result of that effort was the conception of a process model for data fusion and a data fusion lexicon (Hall and Llinas 1997; Blasch et al. 2012). Information and data fusion are mainly supported by sensor networks which present the following advantages over a single sensor:

- Can be deployed over wide regions
- Provide diverse characteristics/viewing angles of the observed phenomenon
- Are more robust to failures
- Gather more data that, once fused, provide a more complete picture of the observed phenomenon

- Allow better geographical coverage, i.e., wider area and less terrain obstructions.

Sensor network architectures can be centralized, hierarchical (with or without feedback), and distributed (peer-to-peer). Today's trend for many monitoring and decision-making tasks is to exploit large-scale networks of low-cost and low-energy consumption devices with sensing, communication, and processing capabilities. For scalability issues, such networks should operate in a fully distributed (peer-to-peer) fashion, i.e., with no centralized coordination, so as to achieve in each node a global estimation/decision objective through localized processing only.

The attainment of this goal actually requires several issues to be addressed like:

- Spatial and temporal sensor alignment
- Scalable fusion
- Robustness with respect to data incest (or double counting), i.e., repeated use of the same information
- Handling data latency (e.g., out-of-sequence measurements/estimates)
- Communication bandwidth limitations

In particular, to counteract data incest the so-called *covariance intersection* (Julier and Uhlmann 1997) robust fusion approach has been proposed to guarantee, at the price of some conservatism, consistency of the fused estimate when combining estimates from different nodes with unknown correlations. For scalable fusion, a consensus approach (Olfati-Saber et al. 2007) can be undertaken. This allows to carry out a global (i.e., over the whole network) processing task by iterating local processing steps among neighboring nodes.

Several consensus algorithms have been proposed for distributed parameter (Calafiore and Abrate 2009) or state (Xiao et al. 2005; Alriksson and Rantzer 2006; Olfati-Saber 2007; Kamgarpour and Tomlin 2007; Stankovic et al. 2009) estimation. Recently, Battistelli and Chisci (2014) introduced a generalized consensus on probability densities which opens up the possibility to perform in a fully distributed and scalable way any Bayesian estimation task over a sensor network. As by-products, this approach allowed to derive consensus Kalman filters with guaranteed stability under minimal requirements of system observability and network connectivity (Battistelli et al. 2011, 2012; Battistelli and Chisci 2014), consensus nonlinear filters (Battistelli et al. 2012), and a consensus CPHD filter for distributed multitarget tracking (Battistelli et al. 2013). Despite these interesting preliminary results, networked estimation is still a very active research area with many open problems related to energy efficiency, estimation performance optimality, robustness with respect to delays and/or data losses, etc.

Quantum Estimation

Quantum estimation theory consists of a generalization of the classical estimation theory in terms of quantum mechanics. As a matter of fact, the statistical theory can be seen as a particular case of the more general quantum theory (Helstrom 1969, 1976). Quantum mechanics presents practical applications in several fields of technology (Personick 1971) such as, the use of quantum number generators in place of the classical random number generators. Moreover,

manipulating the energy states of the cesium atoms, it is possible to suppress the quantum noise levels and consequently improve the accuracy of atomic clocks. Quantum mechanics can also be exploited to solve optimization problems, giving sometimes optimization algorithms that are faster than conventional ones. For instance, McGeoch and Wang (2013) provided an experimental study of algorithms based on quantum annealing. Interestingly, the results of McGeoch and Wang (2013) have shown that this approach allows to obtain better solutions with respect to those found with conventional software solvers. In quantum mechanics, also the Kalman filter has found its proper form, as the quantum Kalman filter. In Iida et al. (2010) the quantum Kalman filter is applied to an optical cavity composed of mirrors and crystals inside, which interacts with a probe laser. In particular, a form of a quantum stochastic differential equation can be written for such a system so as to design the algorithm that updates the estimates of the system variables on the basis of the measurement outcome of the system.

Abstract

Recent developments in computer and communication technologies have led to a new type of large-scale resource-constrained wireless embedded control systems. It is desirable in these systems to limit the sensor and control computation and/or communication to instances when the system needs attention. However, classical sampled-data control is based on performing sensing and actuation periodically rather than when the system needs attention. This article discusses event- and self-triggered control systems where sensing and actuation is performed when needed. Event-triggered control is reactive and generates sensor sampling and control actuation when, for instance, the plant state deviates more than a certain threshold from a desired value. Self-triggered control, on the other hand, is proactive and computes the next sampling or actuation instance ahead of time. The basics of these control strategies are introduced together with references for further reading.

Introduction

In standard control textbooks, e.g., Åström and Wittenmark (1997) and Franklin et al. (2010), periodic control is presented as the only choice for implementing feedback control laws on digital platforms. Although this time-triggered control paradigm has proven to be extremely successful in many digital control applications, recent developments in computer and communication technologies have led to a new type of large-scale resource-constrained (wireless) control systems that call for a reconsideration of this traditional paradigm. In particular, the increasing popularity of (shared) wired and wireless networked control systems raises the importance of explicitly addressing energy, computation, and communication constraints when designing feedback control loops. Aperiodic control strategies that allow the inter-execution times of control tasks to be varying in time offer potential advantages with respect to periodic control when handling these constraints, but they also introduce many new interesting theoretical and practical challenges.

Although the discussions regarding periodic vs. aperiodic implementation of feedback control loops date back to the beginning of computer-controlled systems, e.g., Gupta (1963), in the late 1990s two influential papers (Åström and Bernhardsson 1999; Årzén 1999) highlighted the advantages of *event-based* feedback control. These two papers spurred the development of the first *systematic designs* of event-based implementations of stabilizing feedback control laws, e.g., Yook et al. (2002), Tabuada (2007), Heemels et al. (2008), and Henningsson et al. (2008). Since then, several researchers have improved and generalized these results and alternative approaches have appeared. In the meantime, also so-called *self-triggered* control (Velasco et al. 2003) emerged. Event-triggered and self-triggered control systems consist of two elements, namely, a feedback controller that computes the control input and a triggering mechanism that determines when the control

input has to be updated again. The difference between event-triggered control and self-triggered control is that the former is reactive, while the latter is proactive. Indeed, in event-triggered control, a triggering condition based on current measurements is continuously monitored and when the condition holds, an event is triggered. In self-triggered control the next update time is precomputed at a control update time based on predictions using previously received data and knowledge of the plant dynamics. In some cases, it is advantageous to combine event-triggered and self-triggered control resulting in a control system reactive to unpredictable disturbances and proactive by predicting future use of resources.

Time-Triggered, Event-Triggered and Self-Triggered Control

To indicate the differences between various digital implementations of feedback control laws, consider the control of the nonlinear plant

$$\dot{x} = f(x, u) \quad (1)$$

with $x \in \mathbb{R}^{n_x}$ the state variable and $u \in \mathbb{R}^{n_u}$ the input variable. The system is controlled by a nonlinear state feedback law

$$u = h(x) \quad (2)$$

where $h : \mathbb{R}^{n_x} \rightarrow \mathbb{R}^{n_u}$ is an appropriate mapping that has to be implemented on a digital platform. Recomputing the control value and updating the actuator signals will occur at times denoted by $t_0, t_1, t_2, \dots$ with $t_0 = 0$. If we assume the inputs to be held constant in between the successive recomputations of the control law (referred to as sample-and-hold or zero-order-hold), we have

$$u(t) = u(t_k) = h(x(t_k)) \quad \forall t \in [t_k, t_{k+1}), \quad k \in \mathbb{N}. \quad (3)$$

We refer to the instants $\{t_k\}_{k \in \mathbb{N}}$ as the *triggering* times or *execution* times. Based on these times we can easily explain the difference between

time-triggered control, event-triggered control, and self-triggered control.

In *time-triggered* control we have the equality $t_k = kT_s$ with $T_s > 0$ being the sampling period. Hence, the updates take place equidistantly in time irrespective of how the system behaves. There is no “feedback mechanism” in determining the execution times; they are determined a priori and in “open loop.” Another way of writing the triggering mechanism in time-triggered control is

$$t_{k+1} = t_k + T_s, \quad k \in \mathbb{N} \quad (4)$$

with $t_0 = 0$.

In *event-triggered* control the next execution time of the controller is determined by an event-triggering mechanism that continuously verifies if a certain condition based on the actual state variable becomes true. This condition includes often also information on the state variable $x(t_k)$ at the previous execution time t_k and can be written, for instance, as $C(x(t), x(t_k)) > 0$. Formally, the execution times are then determined by

$$t_{k+1} = \inf\{t > t_k \mid C(x(t), x(t_k)) > 0\} \quad (5)$$

with $t_0 = 0$. Hence, it is clear from (5) that there is a *feedback* mechanism present in the determination of the next execution time as it is based on the measured state variable. In this sense event-triggered control is *reactive*.

Finally, in *self-triggered* control the next execution time is determined *proactively* based on the measured state $x(t_k)$ at the previous execution time. In particular, there is a function $M : \mathbb{R}^{n_x} \rightarrow \mathbb{R}_{\geq 0}$ that specifies the next execution time as

$$t_{k+1} = t_k + M(x(t_k)) \quad (6)$$

with $t_0 = 0$. As a consequence, in self-triggered control both the control value $u(t_k)$ and the next execution time t_{k+1} are computed at execution time t_k . In between t_k and t_{k+1} , no further actions are required from the controller. Note that the time-triggered implementation can be seen as a special case of the self-triggered implementation by taking $M(x) = T_s$ for all $x \in \mathbb{R}^{n_x}$.

Clearly, in all the three implementation schemes T_s , C and M are chosen together with the feedback law given through h to provide stability and performance guarantees and to realize a certain utilization of computer and communication resources.

Lyapunov-Based Analysis

Much work on event-triggered control used one of the following two modeling and analysis frameworks: The perturbation approach and the hybrid system approach.

Perturbation Approach

In the perturbation approach one adopts perturbed models that describe how the event-triggered implementation of the control law perturbs the ideal continuous-time implementation $u(t) = h(x(t))$, $t \in \mathbb{R}_{\geq 0}$. In order to do so, consider the error e given by

$$e(t) = x(t_k) - x(t) \text{ for } t \in [t_k, t_{k+1}), k \in \mathbb{N}. \quad (7)$$

Using this error variable we can write the closed-loop system based on (1) and (3) as

$$\dot{x} = f(x, h(x + e)). \quad (8)$$

Essentially, the three implementations discussed above have their own way of indicating when an execution takes place and the error e is reset to zero. The equation (8) clearly shows how the ideal closed-loop system is *perturbed* by using a time-triggered, event-triggered, or self-triggered implementation of the feedback law in (2). Indeed, when $e = 0$ we obtain the ideal closed loop

$$\dot{x} = f(x, h(x)). \quad (9)$$

The control law in (2) is typically chosen so as to guarantee that the system in (9) has certain global asymptotic stability (GAS) properties. In particular, it is often assumed that there exists a Lyapunov function $V : \mathbb{R}_{n_x} \rightarrow \mathbb{R}_{\geq 0}$ in the sense

that V is positive definite and for all $x \in \mathbb{R}_{n_x}$ we have

$$\frac{\partial V}{\partial x} f(x, h(x)) \leq -\|x\|^2. \quad (10)$$

Note that this inequality is stronger than strictly needed (at least for nonlinear systems), but for pedagogical reasons we choose this simpler formulation. For the perturbed model, the inequality in (10) can in certain cases (including linear systems) be modified to

$$\frac{\partial V}{\partial x} f(x, h(x)) \leq -\|x\|^2 + \beta \|e\|^2 \quad (11)$$

in which $\beta > 0$ is a constant used to indicate how the presence of the implementation error e affects the decrease of the Lyapunov function. Based on (10) one can now choose the function C in (5) to preserve GAS of the event-triggered implementation. For instance, $C(x(t), x(t_k)) = \|x(t_k) - x(t)\| - \sigma \|x(t)\|$, i.e.,

$$t_{k+1} = \inf\{t > t_k \mid \|e(t)\| > \sigma \|x(t)\|\}, \quad (12)$$

assures that

$$\|e\| \leq \sigma \|x\| \quad (13)$$

holds. When $\sigma < 1/\beta$, we obtain from (11) and (13) that GAS properties are preserved for the event-triggered implementation. Besides, under certain conditions provided in Tabuada (2007), a global positive lower bound exists on the inter-execution times, i.e., there exists a $\tau_{\min} > 0$ such that $t_{k+1} - t_k > \tau_{\min}$ for all $k \in \mathbb{N}$ and all initial states x_0 .

Also self-triggered controllers can be derived using the perturbation approach. In this case, stability properties can be guaranteed by choosing M in (6) ensuring that $C(x(t), x(t_k)) \leq 0$ holds for all times $t \in [t_k, t_{k+1})$ and all $k \in \mathbb{N}$.

Hybrid System Approach

By taking as a state variable $\xi = (x, e)$, one can write the closed-loop event-triggered control system given by (1), (3), and (5) as the hybrid impulsive system (Goebel et al. 2009)

$$\dot{\xi} = \begin{pmatrix} f(x, h(x+e)) \\ -f(x, h(x+e)) \end{pmatrix} \text{ when } C(x, x+e) \geq 0 \quad (14a)$$

$$\xi^+ = \begin{pmatrix} x \\ 0 \end{pmatrix} \text{ when } C(x, x+e) \leq 0. \quad (14b)$$

This observation was made in Donkers and Heemels (2010, 2012) and Postoyan et al. (2011). Tools from hybrid system theory can be used to analyze this model, which is more accurate as it includes the error dynamics of the event-triggered closed-loop system. In fact, the stability bounds obtained via the hybrid system approach can be proven to be never worse than ones obtained using the perturbation approach in many cases, see, e.g., Donkers and Heemels (2012), and typically the hybrid system approach provides (strictly) better results in practice. However, in general an analysis via the hybrid system approach is more complicated than using a perturbation approach.

Note that by including a time variable τ , one can also write the closed-loop system corresponding to self-triggered control (1), (3), and (6) as a hybrid system using the state variable $\chi = (x, e, \tau)$. This leads to the model

$$\dot{\chi} = \begin{pmatrix} f(x, h(x+e)) \\ -f(x, h(x+e)) \\ 1 \end{pmatrix} \text{ when } 0 \leq \tau \leq M(x+e) \quad (15a)$$

$$\chi^+ = \begin{pmatrix} x \\ 0 \\ 0 \end{pmatrix} \text{ when } \tau = M(x+e), \quad (15b)$$

which can be used for analysis based on hybrid tools as well.

Alternative Event-Triggering Mechanisms

There are various alternative event-triggering mechanisms. A few of them are described in this section.

Relative, Absolute, and Mixed Triggering Conditions

Above we discussed a very basic event-triggering condition in the form given in (12), which is sometimes called *relative* triggering as the next control task is executed at the instant when the ratio of the norms of the error $\|e\|$ and the measured state $\|x\|$ is larger than or equal to σ . Also *absolute* triggering of the form

$$t_{k+1} = \inf\{t > t_k \mid \|e(t)\| \geq \delta\} \quad (16)$$

can be considered. Here $\delta > 0$ is an absolute threshold, which has given this scheme the name send-on-delta (Miskowicz 2006). Recently, a *mixed* triggering mechanism of the form

$$t_{k+1} = \inf\{t > t_k \mid \|e(t)\| \geq \sigma \|x(t)\| + \delta\}, \quad (17)$$

combining an absolute and a relative threshold, was proposed (Donkers and Heemels 2012). It is particularly effective in the context of output-based control.

Model-Based Triggering

In the triggering conditions discussed so far, essentially the current control value $u(t)$ is based on a *held* value $x(t_k)$ of the state variable, as specified in (3). However, if good model-based information regarding the plant is available, one can use better model-based predictions of the actuator signal. For instance, in the linear context, (Lunze and Lehmann 2010) proposed to use a *control input generator* instead of a plain zero-order hold function. In fact, the plant model was described by

$$\dot{x} = Ax + Bu + Ew \quad (18)$$

with $x \in \mathbb{R}^{n_x}$ the state variable, $u \in \mathbb{R}^{n_u}$ the input variable, and $w \in \mathbb{R}^{n_w}$ a bounded disturbance input. It was assumed that a well functioning state feedback controller $u = Kx$ was available. The control input generator was then based on the model-based predictions given for $[t_k, t_{k+1})$ by

$$\begin{aligned}\dot{x}_s(t) &= (A + BK)x_s(t) + E\hat{w}(t_k) \\ \text{with } x_s(t_k) &= x(t_k)\end{aligned}\quad (19)$$

and $\hat{w}(t_k)$ is an estimate for the (average) disturbance value, which is determined at execution time t_k , $k \in \mathbb{N}$. The applied input to the actuator is then given by $u(t) = Kx_s(t)$ for $t \in [t_k, t_{k+1})$, $k \in \mathbb{N}$. Note that (19) provides a prediction of the closed-loop state evolution using the latest received value of the state $x(t_k)$ and the estimate $\hat{w}(t_k)$ of the disturbances. Also the event-triggering condition is based on this model-based prediction of the state as it is given by

$$t_{k+1} = \inf\{t > t_k \mid \|x_s(t) - x(t)\| \geq \delta\}. \quad (20)$$

Hence, when the prediction $x_s(t)$ diverts to far from the measured state $x(t)$, the next event is triggered so that updates of the state are sent to the actuator. These model-based triggering schemes can enhance the communication savings as they reduce the number of events by using model-based knowledge.

Other model-based event-triggered control schemes are proposed, for instance, in Yook et al. (2002), Garcia and Antsaklis (2013), and Heemels and Donkers (2013).

Triggering with Time-Regularization

Time-regularization was proposed for *output-based* triggering to avoid the occurrence of accumulations in the execution times (Zeno behavior) that would obstruct the existence of a positive lower bound on the inter-execution times $t_{k+1} - t_k$, $k \in \mathbb{N}$. In Tallapragada and Chopra (2012a, b), the triggering update

$$t_{k+1} = \inf\{t > t_k + T \mid \|e(t)\| \geq \sigma \|x(t)\|\} \quad (21)$$

was proposed, where $T > 0$ is a built-in lower bound on the minimal inter-execution times. The authors discussed how T and σ can be designed to guarantee closed-loop stability. In Heemels et al. (2008) a similar triggering was proposed using an absolute-type of triggering.

An alternative to exploiting a built-in lower bound T is combining ideas from time-triggered

control and event-triggering control. Essentially, the idea is to only verify a specific event-triggering condition at certain equidistant time instants kT_s , $k \in \mathbb{N}$, where $T_s > 0$ is the sampling period. Such proposals were mentioned in, for instance, Årzén (1999), Yook et al. (2002), Henningsson et al. (2008), and Heemels et al. (2008, 2013). In this case the execution times are given by

$$\begin{aligned}t_{k+1} &= \inf\{t > t_k \mid t = kT_s, k \in \mathbb{N}, \\ &\text{and } \|e(t)\| \geq \sigma \|x(t)\|\}\end{aligned}\quad (22)$$

in case a relative triggering is used. In Heemels et al. (2013) the term *periodic event-triggered control* was coined for this type of control.

Decentralized Triggering Conditions

Another important extension of the mentioned event-triggered controllers, especially in large-scale networked systems, is the decentralization of the event-triggered control. Indeed, if one focuses on any of the abovementioned event-triggering conditions (take, e.g., (5)), it is obvious that the full state variable $x(t)$ has to be continuously available in a central coordinator to determine if an event is triggered or not. If the sensors that measure the state are physically distributed over a wide area, this assumption is prohibitive for its implementation. In such cases, it is of high practical importance that the event-triggering mechanism can be decentralized and the execution of control tasks can be executed based on local information. One first idea could be to use *local* event-triggering mechanisms for the i -th sensor that measures x_i . One could “decentralize” the condition (5), into

$$t_{k^i+1}^i = \inf\{t > t_{k^i}^i \mid \|e_i(t)\| \geq \sigma \|x_i(t)\|\}, \quad (23)$$

in which $e_i(t) = x_i(t_{k^i}^i) - x_i(t)$ for $t \in [t_{k^i}^i, t_{k^i+1}^i)$, $k^i \in \mathbb{N}$. Note that each sensor now has its own execution times $t_{k^i}^i$, $k^i \in \mathbb{N}$ at which the information $x_i(t)$ is transmitted. More importantly, the triggering condition (23) is based on local data only and does not need a central coordinator having access to the complete state information.

Besides since (23) still guarantees that (13) holds, stability properties can still be guaranteed; see Mazo and Tabuada (2011).

Several other proposals for decentralized event-triggered control schemes were made, e.g., Persis et al. (2013), Wang and Lemmon (2011), Garcia and Antsaklis (2013), Yook et al. (2002), and Donkers and Heemels (2012).

Triggering for Multi-agent Systems

Event-triggered control strategies are suitable for cooperative control of multi-agent systems. In multi-agent systems, local control actions of individual agents should lead to a desirable global behavior of the overall system. A prototype problem for control of multi-agent systems is the agreement problem (also called the consensus or rendezvous problem), where the states of all agents should converge to a common value (sometimes the average of the agents' initial conditions). The agreement problem has been shown to be solvable for certain low-order dynamical agents in both continuous and discrete time, e.g., Olfati-Saber et al. (2007). It was recently shown in Dimarogonas et al. (2012), Shi and Johansson (2011), and Seyboth et al. (2013) that the agreement problem can be solved using event-triggered control. In Seyboth et al. (2013) the triggering times for agent i are determined by

$$t_{ki+1}^i = \inf\{t > t_{ki}^i \mid C_i(x_i(t), x_i(t_{ki}^i)) > 0\}, \quad (24)$$

which should be compared to the triggering times as specified through (5). The triggering condition compares the current state value with the one previously communicated, similarly to the previously discussed decentralized event-triggered control (see (23)), but now the communication is *only* to the agent's neighbors. Using such event-triggered communication, the convergence rate to agreement (i.e., $\|x_i(t) - x_j(t)\| \rightarrow 0$ as $t \rightarrow \infty$ for all i, j) can be maintained with a much lower communication rate than for time-triggered communication.

Outlook

Many simulation and experimental results show that event-triggered and self-triggered control strategies are capable of reducing the number of control task executions, while retaining a satisfactory closed-loop performance. In spite of these results, the actual deployment of these novel control paradigms in relevant applications is still rather marginal. Some exceptions include recent event-triggered control applications in underwater vehicles (Teixeira et al. 2010), process control (Lehmann et al. 2012), and control over wireless networks (Araujo et al. 2014). To foster the further development of event-triggered and self-triggered controllers in the future, it is therefore important to validate these strategies in practice, next to building up a complete system theory for them. Regarding the latter, it is fair to say that, even though many interesting results are currently available, the system theory for event-triggered and self-triggered control is far from being mature, certainly compared to the vast literature on time-triggered (periodic) sampled-data control. As such, many theoretical and practical challenges are ahead of us in this appealing research field.

Evolutionary Games

Eitan Altman

INRIA, Sophia-Antipolis, France

Abstract

Evolutionary games constitute the most recent major mathematical tool for understanding, modelling and predicting evolution in biology and other fields. They complement other well established tools such as branching processes and the Lotka-Volterra (1910) equations (e.g. for the predator - prey dynamics or for epidemics evolution). Evolutionary Games also brings novel features to game theory. First, it focuses on the dynamics of competition rather than restricting attention to the equilibrium. In particular, it tries to explain how an equilibrium emerges. Second, it brings new definitions of stability, that are more adapted to the context of large populations. Finally, in contrast to standard game theory, players are not assumed to be “rational” or “knowledgeable” as to anticipate the other players’ choices. The objective of this article, is to present foundations as well as recent advances in evolutionary games, highlight the novel concepts that they introduce with respect to game theory as formulated by John Nash, and describe through several examples their huge potential as tools for modeling interactions in complex systems.

Evolutionary stable strategies · Fitness · Replicator dynamics

Introduction

Evolutionary game theory is the youngest of several mathematical tools used in describing and modeling evolution. It was preceded by the theory of branching processes (Watson and Francis Galton 1875) and its extensions (Altman 2008)

which have been introduced in order to explain the evolution of family names in the English population of the second half of the nineteenth century. This theory makes use of the probabilistic distribution of the number of offspring of an individual in order to predict the probability at which the whole population would become eventually extinct. It describes the evolution of the number of offsprings of a given individual. The Lotka-Volterra equations (Lotka-Volterra 1910) and their extensions are differential equations that describe the population size of each of several species that have a predator-prey type relation. One of the foundations in evolutionary games (and its extension to population games) which is often used as the starting point in their definition is the replicator dynamics which, similarly to the Lotka-Volterra equations, describe the evolution of the size of various species that interact with each other (or of various behaviors within a given population). In both the Lotka-Volterra equations and in replicator dynamics, the evolution of the size of one type of population may depend on the sizes of all other populations. Yet, unlike the Lotka-Volterra equations, the object of the modeling is the normalized sizes of populations rather than the size itself. By normalized size of some type, we mean the fraction of that type within the whole population. A basic feature in evolutionary games is, thus, that the evolution of the fraction of a given type in the population depends on the sizes of other types only through the normalized size rather than through their actual one.

The relative rate of the decrease or increase of the normalized population size of some type in the replicator dynamics is what we call fitness and is to be understood in the Darwinian sense. If some type or some behavior increases more than another one, then it has a larger fitness. the evolution of the fitness as described by the replicator dynamics is a central object of study in evolutionary games.

So far we did not actually consider any game and just discussed ways of modeling evolution. The relation to game theory is due to the fact that under some conditions, the fitness converges to some fixed limit, which can be

identified as an equilibrium of a matrix game in which the utilities of the players are the fitnesses. This limit is then called an ESS – evolutionary stable strategy – as defined by Maynard Smith and Price in Maynard Smith and Price (1973). It can be computed using elementary tools in matrix games and then used for predicting the (long term) distribution of behaviors within a population. Note that an equilibrium in a matrix game can be obtained only when the players of the matrix game are rational (each one maximizing its expected utility, being aware of the utilities of other players and of the fact that these players maximize their utilities, etc.). A central contribution of evolutionary games is thus to show that evolution of possibly nonrational populations converges under some conditions to the equilibrium of a game played by rational players. This surprising relationship between the equilibrium of a noncooperative matrix game and the limit points of the fitness dynamics has been supported by a rich body of experimental results; see Friedman (1996).

On the importance of the ESS for understanding the evolution of species, Dawkins writes in his book “The Selfish Gene” (Dawkins 1976): “we may come to look back on the invention of the ESS concept as one of the most important advances in evolutionary theory since Darwin.” He further specifies: “Maynard Smith’s concept of the ESS will enable us, for the first time, to see clearly how a collection of independent selfish entities can come to resemble a single organized whole.”

Here we shall follow the nontraditional approach describing evolutionary games: we shall first introduce the replicator dynamics and then introduce the game theoretic interpretation related to it.

Replicator Dynamics

In the biological context, the replicator dynamics is a differential equation that describes the way in which the usage of strategies changes in time. They are based on the idea that the average

growth rate per individual that uses a given strategy is proportional to the excess of fitness of that strategy with respect to the average fitness.

In engineering, the replicator dynamics could be viewed as a rule for updating mixed strategies by individuals. It is a decentralized rule since it only requires knowing the average utility of the population rather than the strategy of each individual.

Replicator dynamics is one of the most studied dynamics in evolutionary game theory. It has been introduced by Taylor and Jonker (1978). The replicator dynamics has been used for describing the evolution of road traffic congestion in which the fitness is determined by the strategies chosen by all drivers (Sandholm 2009). It has also been studied in the context of the association problem in wireless communications (Shakkottai et al. 2007).

Consider a set of N strategies and let $p_j(t)$ be the fraction of the whole population that uses strategy j at time t . Let $p(t)$ be the corresponding N -dimensional vector. A function f_j is associated with the growth rate of strategy j , and it is assumed to depend on the fraction of each of the N strategies in the population. There are various forms of replicator dynamics (Sandholm 2009) and we describe here the one most commonly used. It is given by

$$\dot{p}_j(t) = \mu p_j(t) \left[f_j(p(t)) - \sum_{k=1}^N p_k(t) f_k(p(t)) \right], \quad (1)$$

where μ is some positive constant and the payoff function f_k is called the fitness of strategy k .

In evolutionary games, evolution is assumed to be due to pairwise interactions between players, as will be described in the next section. Therefore, f_k has the form $f_k(p) = \sum_{i=1}^N J(k, i) p(i)$ where $J(k, i)$ is the fitness of an individual playing k if it interacts with an individual that plays strategy i .

Within quite general settings (Weibull 1995), the above replicator dynamics is known to converge to an ESS (which we introduce in the next section).

Evolutionary Games: Fitnesses

Consider an infinite population of players. Each individual i plays at times t_n^i , $n = 1, 2, 3, \dots$ (assumed to constitute an independent Poisson process with some rate λ) a matrix game against some player $j(n)$ randomly selected within the population. The choice $j(n)$ of the other players at different times is independent. All players have the same finite space of pure strategies (also called actions) K . Each time it plays, a player may use a mixed strategy p , i.e., a probability measure over the set of pure strategies. We consider $J(k, i)$ (defined in the previous section) to be the payoff for a tagged individual if it uses a strategy k , and it interacts with an individual using strategy i . With some abuse of notation, one denotes by $J(p, q)$ the expected payoff for a player who uses a mixed strategy p when meeting another individual who adopts the mixed strategy q . If we define a payoff matrix A and consider p and q to be column vectors, then $J(p, q) = p'Aq$. The payoff function J is indeed linear in p and q . A strategy q is called a Nash equilibrium if

$$\forall p \in \Delta(K), \quad J(q, q) \geq J(p, q) \quad (2)$$

where $\Delta(K)$ is the set of probabilities over the set K .

Suppose that the whole population uses a strategy q and that a small fraction ϵ (called “mutations”) adopts another strategy p . Evolutionary forces are expected to select against p if

$$J(q, \epsilon p + (1 - \epsilon)q) > J(p, \epsilon p + (1 - \epsilon)q). \quad (3)$$

Evolutionary Stable Strategies: ESS

Definition 1 q is said to be an evolutionary stable strategy (ESS) if for every $p \neq q$ there exists some $\bar{\epsilon}_p > 0$ such that (3) holds for all $\epsilon \in (0, \bar{\epsilon}_p)$.

The definition of ESS is thus related to a robustness property against deviations by a whole (possibly small) fraction of the population. This is an important difference that distinguishes the equilibrium in populations as seen by biologists and the standard Nash equilibrium often used in

economics context, in which robustness is defined against the possible deviation of a single user. Why do we need the stronger type of robustness? Since we deal with large populations, it is likely to be expected that from time to time, some group of individuals may deviate. Thus robustness against deviations by a single user is not sufficient to ensure that deviations will not develop and end up being used by a growing portion of the population.

Often ESS is defined through the following equivalent definition.

Theorem 1 (Weibull 1995, Proposition 2.1 or Hofbauer and Sigmund 1998, Theorem 6.4.1, p 63) *A strategy q is said to be an evolutionary stable strategy if and only if $\forall p \neq q$ one of the following conditions holds:*

$$J(q, q) > J(p, q), \quad (4)$$

or

$$J(q, q) = J(p, q) \text{ and } J(q, p) > J(p, p). \quad (5)$$

In fact, if condition (4) is satisfied, then the fraction of mutations in the population will tend to decrease (as it has a lower fitness, meaning a lower growth rate). Thus, the strategy q is then immune to mutations. If it does not but if still the condition (5) holds, then a population using q is “weakly” immune against a mutation using p . Indeed, if the mutant’s population grows, then we shall frequently have individuals with strategy q competing with mutants. In such cases, the condition $J(q, p) > J(p, p)$ ensures that the growth rate of the original population exceeds that of the mutants.

A mixed strategy q that satisfies (4) for all $p \neq q$ is called strict Nash equilibrium. Recall that a mixed strategy q that satisfies (2) for all $p \neq q$ is a Nash equilibrium. We conclude from the above theorem that being a strict Nash equilibrium implies being an ESS, and being an ESS implies being a Nash equilibrium. Note that whereas a mixed Nash equilibrium is known to exist in a matrix game, an ESS may not exist. However, an ESS is known to exist in

evolutionary games where the number of strategies available to each player is 2 (Weibull 1995).

Proposition 1 *In a symmetric game with two strategies for each player and no pure Nash equilibrium, there exists a unique mixed Nash equilibrium which is an ESS.*

Example: The Hawk and Dove Game

We briefly describe the hawk and dove game (Maynard Smith and Price 1973). A bird that searches food finds itself competing with another bird over food and has to decide whether to adopt a peaceful behavior (dove) or an aggressive one (hawk). The advantage of behaving aggressively is that in an interaction with a peaceful bird, the aggressive one gets access to all the food. This advantage comes at a cost: a hawk which meets another hawk ends up fighting with it and thus takes a risk of getting wounded. In contrast, two doves that meet in a contest over food share it without fighting. The fitnesses for player 1 (who chooses a row) are summarized in Table 1, in which the cost for fighting is taken to be some parameter $\delta > 1/2$.

This game has a unique mixed Nash equilibrium (and thus a unique ESS) in which the fraction p of aggressive birds is given by

$$p = \frac{2}{1.5 + \delta}$$

Extension: Evolutionary Stable Sets

Assume that there are two mixed strategies p_i and p_j that have the same performance against each other, i.e., $J(p_i, p_j) = J(p_j, p_j)$. Then neither one of them can be an ESS, even if they are quite robust against other strategies. Now assume that when excluding one of them from the set

of mixed strategies, the other one is an ESS. This could imply that different combinations of these two ESS's could coexist and would together be robust to any other mutations. This motivates the following definition of an ESSet (Cressman 2003):

Definition 2 A set E of symmetric Nash equilibria is an evolutionarily stable set (ESSet) if, for all $q \in E$, we have $J(q, p) > J(p, p)$ for all $p \notin E$ and such that $J(p, q) = J(q, q)$.

Properties of ESSet:

- (i) For all p and p' in an ESSet E , we have $J(p', p) = J(p, p)$.
- (ii) If a mixed strategy is an ESS, then the singleton containing that mixed strategy is an ESSet.
- (iii) If the ESSet is not a singleton, then there is no ESS.
- (iv) If a mixed strategy is in an ESSet, then it is a Nash equilibrium (see Weibull 1995, p. 48, Example 2.7).
- (v) Every ESSet is a disjoint union of Nash equilibria.
- (vi) A perturbation of a mixed strategy which is in the ESSet can move the system to another mixed strategy in the ESSet. In particular, every ESSet is asymptotically stable for the replicator dynamics (Cressman 2003).

Summary and Future Directions

The entry has provided an overview of the foundations of evolutionary games which include the ESS (evolutionary stable strategy) equilibrium concept that is stronger than the standard Nash equilibrium and the modeling of the dynamics of the competition through the replicator dynamics. Evolutionary game framework is a first step in linking game theory to evolutionary processes. The payoff of a player is identified as its fitness, i.e., the rate of reproduction. Further development of this mathematical tool is needed for handling hierarchical fitness, i.e., the cases where the individual that interacts cannot be directly

Evolutionary Games, Table 1 The hawk-dove game

	H	D
H	$1/2 - \delta$	1
D	0	$1/2$

identified with the reproduction as it is part of a larger body. For example, the behavior of a blood cell in the human body when interacting with a virus cannot be modeled as directly related to the fitness of the blood cell but rather to that of the human body. A further development of the theory of evolutionary games is needed to define meaningful equilibrium notions and relate them to replication in such contexts.

Experiment Design and Identification for Control

Håkan Hjalmarsson

School of Electrical Engineering and Computer Science, Centre for Advanced Bioproduction, KTH Royal Institute of Technology, Stockholm, Sweden

Abstract

The experimental conditions have a major impact on the estimation result. Therefore, the available degrees of freedom in this respect that are at the disposal to the user should be used wisely. This entry provides the fundamentals for the available techniques. We also briefly discuss the particulars of identification for model-based control, one of the main applications of system identification.

Keywords

Adaptive experiment design · Application-oriented experiment design · Cramér-Rao lower bound · Crest factor · Experiment design · Fisher information matrix · Identification for control · Least-costly identification · Multisine · Pseudorandom binary signal (PRBS) · Robust experiment design

Introduction

The accuracy of an identified model is governed by:

- (i) Information content in the data used for estimation
- (ii) The complexity of the model structure

The former is related to the noise properties and the “energy” of the external excitation of the system and how it is distributed. In regard to (ii), a model structure which is not flexible enough to capture the true system dynamics will give rise to a systematic error, while an overly flexible model will be overly sensitive to noise (so-called overfitting). The model complexity is closely associated with the number of parameters used. For a linear model structure with n parameters modeling the dynamics, it follows from the invariance result in Rojas et al. (2009) that to obtain a model for which the variance of the frequency function estimate is less than $1/\gamma$ over all frequencies, the signal-to-noise ratio, as measured by input energy over noise variance, must be at least $n\gamma$. With energy being power $\times$ time and as input power is limited in physical systems, this indicates that the experiment time grows at least linearly with the number of model parameters. When the input energy budget is limited, the only way around this problem is to sacrifice accuracy over certain frequency intervals. The methodology to achieve this in a systematic way is known as experiment design.

Model Quality Measures

The Cramér-Rao bound provides a lower bound on the covariance matrix of the estimation error for an unbiased estimator. With $\hat{\theta}_N \in \mathbb{R}^n$ denoting the parameter estimate (based on N input-output samples) and θ_o the true parameters,

$$NE \left[\left(\hat{\theta}_N - \theta_o \right) \left(\hat{\theta}_N - \theta_o \right)^T \right] \geq N I_F^{-1}(\theta_o, N) \quad (1)$$

where $I_F(\theta_o, N) \in \mathbb{R}^{n \times n}$ appearing in the lower bound is the so-called Fisher information matrix (Ljung 1999). For consistent estimators, i.e., when $\hat{\theta}_N \rightarrow \theta_o$ as $N \rightarrow \infty$, the inequality (1) typically holds asymptotically as the sample size N grows to infinity. The right-hand side in (1) is then replaced by the inverse of the per sample Fisher information $I_F(\theta_o) := \lim_{N \rightarrow \infty} I_F(\theta_o, N)/N$. An estimator is said to be asymptotically efficient if equality is reached in (1) as $N \rightarrow \infty$.

Even though it is possible to reduce the mean-square error by constraining the model flexibility appropriately, it is customary to use consistent estimators since the theory for biased estimators is still not well understood. For such estimators, using some function of the Fisher information as performance measure is natural.

General-Purpose Quality Measures

Over the years a number of “general-purpose” quality measures have been proposed. Perhaps the most frequently used is the determinant of the inverse Fisher information. This represents the volume of confidence ellipsoids for the parameter estimates and minimizing this measure is known as D-optimal design. Two other criteria relating to confidence ellipsoids are E-optimal design, which uses the length of the longest principal axis (the minimum eigenvalue of I_F) as quality measure, and A-optimal design, which uses the sum of the squared lengths of the principal axes (the trace of I_F^{-1}).

Application-Oriented Quality Measures

When demands are high and/or experimentation resources are limited, it is necessary to tailor the experiment carefully according to the intended use of the model. Below we will discuss a couple of closely related application-oriented measures.

Average Performance Degradation

Let $V_{\text{app}}(\theta) \geq 0$ be a measure of how well the model corresponding to parameter θ performs when used in the application. In finance, V_{app} can, e.g., represent the ability to predict the stock market. In process industry, V_{app} can

represent the profit gained using a feedback controller based on the model corresponding to θ . Let us assume that V_{app} is normalized such that $\min_{\theta} V_{\text{app}}(\theta) = V_{\text{app}}(\theta_o) = 0$. That V_{app} has minimum corresponding to the parameters of the true system is quite natural. We will call V_{app} the application cost. Assuming that the estimator is asymptotically efficient, using a second-order Taylor approximation gives that the average application cost can be expressed as (the first-order term vanishes since θ_o is the minimizer of V_{app})

$$\begin{aligned} E[V_{\text{app}}(\hat{\theta}_N)] &\approx \frac{1}{2} E\left[(\hat{\theta}_N - \theta_o)^T V''_{\text{app}}(\theta_o) (\hat{\theta}_N - \theta_o) \right] \\ &= \frac{1}{2N} \text{Tr} \left\{ V''_{\text{app}}(\theta_o) I_F^{-1}(\theta_o) \right\} \end{aligned} \quad (2)$$

This is a generalization of the A-optimal design measure, and its minimization is known as L-optimal design.

Acceptable Performance

Alternatively, one may define a set of acceptable models, i.e., a set of models which will give acceptable performance when used in the application. With a performance degradation measure defined of the type V_{app} above, this would be a level set

$$\mathcal{E}_{\text{app}} = \left\{ \theta : V_{\text{app}}(\theta) \leq \frac{1}{\gamma} \right\} \quad (3)$$

for some constant $\gamma > 0$. The objective of the experiment design is then to ensure that the resulting estimate ends up in $\mathcal{E}_{\text{app}}$ with high probability.

Design Variables

In an identification experiment, there are a number of design variables at the user's disposal. Below we discuss three of the most important ones.

Sampling Interval

For the sampling interval, the general advice from an information theoretic point of view is to sample as fast as possible (Ljung 1999). However, sampling much faster than the time constants of the system may lead to numerical issues when estimating discrete time models as there will be poles close to the unit circle. Downsampling may thus be required.

Feedback

Generally speaking, feedback has three effects from an identification and experiment design point of view:

- (i) Not all the power in the input can be used to estimate the system dynamics when a noise model is estimated as a part of the input signal has to be used for the latter task; see Section 8.1 in Forssell and Ljung (1999). When a very flexible noise model is used, the estimate of the system dynamics then has to rely almost entirely on external excitation.
- (ii) Feedback can reduce the effect of disturbances and noise at the output. When there are constraints on the outputs, this allows for larger (input) excitation and therefore more informative experiments.
- (iii) The cross-correlation between input and noise/disturbances requires good noise models to avoid biased estimates (Ljung 1999).

Strictly speaking, (i) is only valid when the system and noise models are parametrized separately. Items (i) and (ii) imply that when there are constraints on the input only, then the optimal design is always in open loop, whereas for output constrained only problems, the experiment should be conducted in closed loop (Agüero and Goodwin 2007).

External Excitation Signals

The most important design variable is the external excitation, including the length of the experiment. Even for moderate experiment lengths, solving optimal experiment design problems with

respect to the entire excitation sequence can be a formidable task. Fortunately, for experiments of reasonable length, the design can be split up in two steps:

- (i) First, optimization of the probability density function of the excitation
- (ii) Generation of the actual sequence from the obtained density function through a stochastic simulation procedure

More details are provided in section “[Computational Issues](#).”

Experimental Constraints

An experiment is always subject to constraints, physical as well as economical. Such constraints are typically translated into constraints on the following signal properties:

- (i) *Variability*. For example, too high level of excitation may cause the end product to go off-spec, resulting in product waste and associated high costs.
- (ii) *Frequency content*. Often, too harsh movements of the inputs may damage equipment.
- (iii) *Amplitudes*. For example, actuators have limited range, restricting input amplitudes.
- (iv) *Waveforms*. In process industry, it is not uncommon that control equipment limits the type of signals that can be applied. In other applications, it may be physically possible to realize only certain types of excitation. See section “[Waveform Generation](#)” for further discussion.

It is also often desired to limit the experiment time so that the process may go back to normal operation, reducing, e.g., cost of personnel. The latter is especially important in the process industry where dynamics are slow. The above type of constraints can be formulated as constraints on the design variables in section “[Design Variables](#)” and associated variables.

Experiment Design Criteria

There are two principal ways to define an optimal experiment design problem:

- (i) *Best effort*. Here the best quality as, e.g., given by one of the quality measures in section “[Model Quality Measures](#)” is sought under constraints on the experimental effort and cost. This is the classical problem formulation.
- (ii) *Least-costly*. The cheapest experiment is sought that results in a predefined model quality. Thus, as compared to best effort design, the optimization criterion and constraint are interchanged. This type of design was introduced by Bombois and coworkers; see Bombois et al. (2006).

As shown in Rojas et al. (2008), the two approaches typically lead to designs only differing by a scaling factor.

Computational Issues

The optimal experiment design problem based on the Fisher information is typically non-convex. For example, consider a finite-impulse response model subject to an experiment of length N with the measured outputs collected in the vector

$$Y = \Phi\theta + E, \quad \Phi = \begin{bmatrix} u(0) & \dots & u(-(n-1)) \\ \vdots & \vdots & \vdots \\ u(N-1) & \dots & u(N-n) \end{bmatrix}$$

where $E \in \mathbb{R}^N$ is zero-mean Gaussian noise with covariance matrix $\sigma^2 I_{N \times N}$. Then it holds that

$$I_F(\theta_o, N) = \frac{1}{\sigma^2} \Phi^T \Phi \quad (4)$$

From an experiment design point of view, the input vector $u = [u(-(n-1)) \dots u(N)]^T$ is the design variable, but with the elements of $I_F(\theta_o, N)$ being a quadratic function of the input

sequence, all typical quality measures become non-convex.

While various methods for non-convex numerical optimization can be used to solve such problems, they often encounter problems with, e.g., local minima. To address this, a number of techniques have been developed either where the problem is reparametrized so that it becomes convex or where a convex approximation is used. The latter technique is called convex relaxation and is often based on a reparametrization as well. We use the example above to provide a flavor of the different techniques.

Reparametrization

If the input is constrained to be periodic so that $u(t) = u(t + N)$, $t = -n, \dots, -1$, it follows that the Fisher information is linear in the sample correlations of the input. Using these as design variables instead of u results in that all quality measures referred to above become convex functions.

This reparametrization thus results in the two-step procedure discussed in section “[External Excitation Signals](#)”: First, the sample correlations are obtained from an optimal experiment design problem, and then an input sequence is generated that has this sample correlation. In the second step, there is a considerable freedom. Notice, however, that since correlations do not directly relate to the actual amplitudes of the resulting signals, it is difficult to incorporate waveform constraints in this approach. On the contrary, variance constraints are easy to incorporate.

Convex Relaxations

There are several approaches to obtain convex relaxations.

Using the per Sample Fisher Information

If the input is a realization of a stationary random process and the sample size N is large enough, $I_F(\theta_o, N)/N$ is approximately equal to the per sample Fisher matrix which only depends on the correlation sequence of the input. Using this approximation, one can now follow the same procedure as in the reparametrization approach and first optimize the input correlation sequence.

The generation of a stationary signal with a certain correlation is a stochastic realization problem which can be solved using spectral factorization followed by filtering white noise sequence, i.e., a sequence of independent identically distributed random variables, through the (stable) spectral factor (Jansson and Hjalmarsson 2005).

More generally, it turns out that the per sample Fisher information for linear models/systems only depends on the joint input/noise spectrum (or the corresponding correlation sequence). A linear parametrization of this quantity thus typically leads to a convex problem (Jansson and Hjalmarsson 2005).

The set of all spectra is infinite dimensional, and this precludes a search over all possible spectra. However, since there is a finite-dimensional parametrization of the per sample Fisher information (it is a symmetric $n \times n$ matrix), it is also possible to find finite-dimensional sets of spectra that parametrize all possible per sample Fisher information matrices. Multisine with appropriately chosen frequencies is one possibility. However, even though all per sample Fisher information matrices can be generated, the solution may be suboptimal depending on which constraints the problem contains.

The situation for nonlinear problems is conceptually the same, but here the entire probability density function of the stationary process generating the input plays the same role as the spectrum in the linear case. This is a much more complicated object to parametrize.

Lifting

An approach that can deal with amplitude constraints is based on a so-called lifting technique: Introduce the matrix $U = uu^T$, representing all possible products of the elements of u . This constraint is equivalent to

$$\begin{bmatrix} U & u \\ u^T & 1 \end{bmatrix} \succeq 0, \quad \text{rank} \begin{bmatrix} U & u \\ u^T & 1 \end{bmatrix} = 1 \quad (5)$$

The idea of lifting is now to observe that the Fisher information matrix is linear in the elements of U and by dropping the rank constraint in (5) a convex relaxation is obtained, where both

U and u (subject to the matrix inequality in (5)) are decision variables.

Frequency-by-Frequency Design

An approximation for linear systems that allows frequency-by-frequency design of the input spectrum and feedback is obtained by assuming that the model is of high order. Then the variance of an n th-order estimate, $G(e^{i\omega}, \hat{\theta}_N)$, of the frequency function can approximately be expressed as

$$\text{Var } G(e^{i\omega}, \hat{\theta}_N) \approx \frac{n}{N} \frac{\Phi_v(\omega)}{\Phi_u(\omega)} \quad (6)$$

([System Identification: An Overview](#)) in the open-loop case (there is a closed-loop extension as well), where Φ_u and Φ_v are the input and noise spectra, respectively. Performance measures of the type (2) can then be written as

$$\int_{-\pi}^{\pi} W(e^{i\omega}) \frac{\Phi_v(\omega)}{\Phi_u(\omega)} d\omega$$

where the weighting $W(e^{i\omega}) \geq 0$ depends on the application. When only variance constraints are present, such problems can be solved frequency by frequency, providing both simple calculations and insight into the design.

Implementation

We have used the notation $I_F(\theta_o, N)$ to indicate that the Fisher information typically (but not always) depends on the parameter corresponding to the true system. That the optimal design depends on the to-be identified system is a fundamental problem in optimal experiment design. There are two basic approaches to address this problem which are covered below. Another important aspect is the choice of waveform for the external excitation signal. This is covered last in this section.

Robust Experiment Design

In robust experiment design, it is assumed that it is known beforehand that the true parameter belongs to some set, i.e., $\theta_o \in \Theta$. A minimax

approach is then typically taken, finding the experiment that minimizes the worst performance over the set Θ . Such optimization problems are computationally very difficult.

Adaptive Experiment Design

The alternative to robust experiment design is to perform the design adaptively or sequentially, meaning that first a design is performed based on some initial “guess” of the true parameter, and then as samples are collected, the design is revised taking advantage of the data information. Interestingly, the convergence rate of the parameter estimate is typically sufficiently fast that for this approach the asymptotic distribution is the same as for the design based on the true model parameter (Hjalmarsson 2009).

Waveform Generation

We have argued above that it is the spectrum of the excitation (together with the feedback) that determines the achieved model accuracy in the linear time-invariant case. In section “[Using the per Sample Fisher Information](#),” we argued that a signal with a particular spectrum can be obtained by filtering a white noise sequence through a stable spectral factor of the desired spectrum. However, we have also in section “[Experimental Constraints](#)” argued that particular applications may require particular waveforms. We will here elaborate further on how to generate a waveform with desired characteristics.

From an accuracy point of view, there are two general issues that should be taken into account when the waveform is selected:

- *Persistence of excitation.* A signal with a spectrum having n nonzero frequencies (on the interval $(-\pi, \pi]$) can be used to estimate at most n parameters. Thus, as is typically the case, if there is uncertainty regarding which model structure to use before the experiment, one has to ensure that a sufficient number of frequencies is excited.
- *The crest factor.* For all systems, the maximum input amplitude, say A , is constrained. To deal with this from an experiment design point of

view, it is convenient to introduce what is called the crest factor of a signal:

$$C_r^2 = \frac{\max_t u^2(t)}{\lim_{N \rightarrow \infty} \frac{1}{N} \sum_{t=1}^N u^2(t)}$$

The crest factor is thus the ratio between the squared maximum amplitude and the power of the signal. Now, for a class of signal waveforms with a given crest factor, the input power that can be used is upper-bounded by

$$\lim_{N \rightarrow \infty} \frac{1}{N} \sum_{t=1}^N u^2(t) \leq \frac{A^2}{C_r^2} \quad (7)$$

However, the power is the integral of the signal spectrum, and since increasing the amplitude of the input signal spectrum will increase a model's accuracy, cf. (6), it is desirable to use as much signal power as possible. By (7) we see that this means that waveforms with low crest factor should be used.

A lower bound for the crest factor is readily seen to be 1. This bound is achieved for binary symmetric signals. Unfortunately, there exists no systematic way to design a binary sequence that has a prescribed spectrum. However, the so-called arcsin law may be used. It states that the sign of a zero-mean Gaussian process with correlation sequence r_τ gives a binary signal having correlation sequence $\tilde{r}_\tau = 2/\pi \arcsin(r_\tau)$. With $\tilde{r}_\tau$ given, one can try to solve this relation for the corresponding r_τ .

A crude, but often sufficient, method to generate binary sequences with desired spectral content is based on the use of *pseudorandom binary signals* (PRBS). Such signals (which are generated by a shift register) are periodic signals which have correlation sequences similar to random white noise, i.e., a flat spectrum. By resampling such sequences, the spectrum can be modified. It should be noted that binary sequences are less attractive when it comes to identifying nonlinearities. This is easy to understand by considering a static system. If only one amplitude of the input is

used, it will be impossible to determine whether the system is nonlinear or not.

A PRBS is a periodic signal and can therefore be split into its Fourier terms. With a period of M , each such term corresponds to one frequency on the grid $2\pi k/M$, $k = 0, \dots, M-1$. Such a signal can thus be used to estimate at most M parameters. Another way to generate a signal with period M is to add sinusoids corresponding to the above frequencies, with desired amplitudes. A periodic signal generated in this way is commonly referred to as a *Multisine*. The crest factor of a multisine depends heavily on the relation between the phases of the sinusoids, times the number of sinusoids. It is possible to optimize the crest factor with respect to the choice of phases (Rivera et al. 2009). There exist also simple deterministic methods for choosing phases that give a good crest factor, e.g., Schroeder phasing. Alternatively, phases can be drawn randomly and independently, giving what is known as random-phase multisines (Pintelon and Schoukens 2012), a family of random signals with properties similar to Gaussian signals. Periodic signals have some useful features:

- *Estimation of nonlinearities.* A linear time-invariant system responds to a periodic input signal with a signal consisting of the same frequencies but with different amplitudes and phases. Thus, it can be concluded that the system is nonlinear if the output contains other frequencies than the input. This can be explored in a systematic way to estimate also the nonlinear part of a system.
- *Estimation of noise variance.* For a linear time-invariant system, the difference in the output between different periods is due entirely to the noise if the system is in steady state. This can be used to devise simple methods to estimate the noise level.
- *Data compression.* By averaging measurements over different periods, the noise level can be reduced at the same time as the number of measurements is reduced.

Further details on waveform generation and general-purpose signals useful in system

identification can be found in Pintelon and Schoukens (2012) and Ljung (1999).

Implications for the Identification Problem Per Se

In order to get some understanding of how optimal experimental conditions influence the identification problem, let us return to the finite-impulse response model example in section “Computational Issues.” Consider a least-costly setting with an acceptable performance constraint. More specifically, we would like to use the minimum input energy that ensures that the parameter estimate ends up in a set of the type (3). An approximate solution to this is that a 99 % confidence ellipsoid for the resulting estimate is contained in $\mathcal{E}_{\text{app}}$. Now, it can be shown that a confidence ellipsoid is a level set for the average least-squares cost $E[V_N(\theta)] = E[\|Y - \Phi\theta\|^2] = \|\theta - \theta_o\|_{\Phi^T \Phi}^2 + \sigma^2$. Assuming the application cost V_{app} also is quadratic in θ , it follows after a little bit of algebra (see Hjalmarsson 2009) that it must hold that

$$E[V_N(\theta)] \geq \sigma^2 (1 + \gamma c V_{\text{app}}(\theta)), \quad \forall \theta \quad (8)$$

for a constant c that is not important for our discussion. The value of $E[V_N(\theta)] = \|\theta - \theta_o\|_{\Phi^T \Phi}^2 + \sigma^2$ is determined by how large the weighting $\Phi^T \Phi$ is, which in turn depends on how large the input u is. In a least-costly setting with the energy $\|u\|^2$ as criterion, the best solution would be that we have equality in (8). Thus we see that optimal experiment design tries to shape the identification criterion after the application cost. We have the following implications of this result:

- (i) *Perform identification under appropriate scaling of the desired operating conditions.* Suppose that $V_{\text{app}}(\theta)$ is a function of how the system outputs deviate from a desired trajectory (determined by θ_o). Performing an experiment which performs the desired trajectory then gives that the sum of the squared prediction errors are an approximation of $V_{\text{app}}(\theta)$, at least for

parameters close to θ_o . Obtaining equality in (8) typically requires an additional scaling of the input excitation or the length of the experiment. The result is intuitively appealing: The desired operating conditions should reveal the system properties that are important in the application.

- (ii) *Identification cost for application performance.* We see that the required energy grows (almost) linearly with γ , which is a measure of how close to the ideal performance (using the true parameter θ_o) we want to come. Furthermore, it is typical that as the performance requirements in the application increase, the sensitivity to model errors increases. This means that $V_{\text{app}}(\theta)$ increases, which thus in turn means that the identification cost increases. In summary, the identification cost will be higher, the higher performance that is required in the application. The inequality (8) can be used to quantify this relationship.
- (iii) *Model structure sensitivity.* As V_{app} will be sensitive to system properties important for the application, while insensitive to system properties of little significance, with the identification criterion V_N matched to V_{app} , it is only necessary that the model structure is able to model the important properties of the system.

In any case, whatever model structure that is used, the identified model will be the best possible in that structure for the intended application. This is very different from an arbitrary experiment where it is impossible to control the model fit when a model of restricted complexity is used.

We conclude that optimal experiment design simplifies the overall system identification problem.

Identification for Control

Model-based control is one of the most important applications of system identification. Robust control ensures performance and stability in the presence of model uncertainty. However, the

majority of such design methods do not employ the parametric ellipsoidal uncertainty sets resulting from standard system identification. In fact only in the last decade analysis and design tools for such type of model uncertainty have started to emerge, e.g., Raynaud et al. (2000) and Gevers et al. (2003).

The advantages of matching the identification criterion to the application have been recognized since long in this line of research. For control applications this typically implies that the identification experiment should be performed under the same closed-loop operation conditions as the controller to be designed. This was perhaps first recognized in the context of minimum variance control (see Gevers and Ljung 1986) where variance errors were the concern. Later on this was recognized to be the case also for the bias error, although here pre-filtering can be used to achieve the same objective.

To account for that the controller to be designed is not available, techniques where control and identification are iterated have been developed, cf. adaptive experiment design in section “[Adaptive Experiment Design](#).” Convergence of such schemes has been established when the true system is in the model set but has proved out of reach for models of restricted complexity.

In recent years, techniques integrating experiment design and model predictive control have started to appear. A general-purpose design criterion is used in Rathouský and Havlena (2013), while Larsson et al. (2013) uses an application-oriented criterion.

Summary and Future Directions

When there is the “luxury” to design the experiment, then this opportunity should be seized by the user. Without informative data there is little that can be done. In this exposé we have outlined the techniques that exist but also emphasized that a well-conceived experiment, reflecting the intended application, significantly can simplify the overall system identification problem.

Further developments of computational techniques are high on the agenda, e.g., how to handle

time-domain constraints and nonlinear models. To this end, developments in optimization methods are rapidly being incorporated. While, as reported in Hjalmarsson (2009), there are some results on how the identification cost depends on the performance requirements in the application, further understanding of this issue is highly desirable. Theory and further development of the emerging model predictive control schemes equipped with experiment design may very well be the direction that will have most impact in practice. Nonparametric kernel methods have proven to be highly competitive estimation methods and developments of experiment design methods for such estimators only started recently in the system identification community; see, e.g., Fujimoto et al. (2018).

Explicit Model Predictive Control

Alberto Bemporad

IMT Institute for Advanced Studies Lucca,
Lucca, Italy

Abstract

Model predictive control (MPC) has been used in the process industries for more than 40 years because of its ability to control multivariable systems in an optimized way under constraints on input and output variables. Traditionally, MPC requires the solution of a quadratic program (QP) online to compute the control action, sometimes restricting its applicability to slow processes. Explicit MPC completely removes the need for online solvers by precomputing the control law off-line, so that online operations reduce to a simple function evaluation. Such a function is piecewise affine in most cases, so that the MPC controller is equivalently

expressed as a lookup table of linear gains, a form that is extremely easy to code, requires only basic arithmetic operations, and requires a maximum number of iterations that can be exactly computed a priori.

Keywords

Constrained control · Embedded optimization · Model predictive control · Multiparametric programming · Quadratic programming

Introduction

Model predictive control (MPC) is a well-known methodology for synthesizing feedback control laws that optimize closed-loop performance subject to prespecified operating constraints on inputs, states, and outputs (Mayne and Rawlings 2009; Borrelli et al. 2017). In MPC, the control action is obtained by solving a finite horizon open-loop optimal control problem at each sampling instant. Each optimization yields a sequence of optimal control moves, but only the first move is applied to the process: At the next time step, the computation is repeated over a shifted time horizon by taking the most recently available state information as the new initial condition of the new optimal control problem. For this reason, MPC is also called “receding horizon control.” In most practical applications, MPC is based on a linear discrete-time time-invariant model of the controlled system and quadratic penalties on tracking errors and actuation efforts; in such a formulation, the optimal control problem can be recast as a quadratic programming (QP) problem, whose linear term of the cost function and right-hand side of the constraints depend on a vector of parameters that may change from one step to another (such as the current state and reference signals). To enable the implementation of MPC in real industrial products, a QP solution method must be embedded in the control hardware. The method must be fast enough to provide a solution within short sampling intervals and require

simple hardware, limited memory to store the data defining the optimization problem and the code implementing the algorithm itself, a simple program code, and good worst-case estimates of the execution time to meet real-time system requirements.

Several *online* solution algorithms have been studied for embedding quadratic optimization in control hardware, such as active-set methods (Ricker 1985; Bemporad 2016), interior-point methods (Wang and Boyd 2010), fast gradient-projection methods (Patrinos and Bemporad 2014), and the alternating direction method of multipliers (Banjac et al. 2017). Explicit MPC takes a different approach to meet the above requirements, where multiparametric quadratic programming is proposed to pre-solve the QP *off-line*, therefore converting the MPC law into a continuous and piecewise-affine function of the parameter vector (Bemporad et al. 2002b; Bemporad 2015). We review the main ideas of explicit MPC in the next section, referring the reader to Alessio and Bemporad (2009) for a more complete survey paper on explicit MPC.

Model Predictive Control Problem

Consider the following finite-time optimal control problem formulation for MPC:

$$V^*(p) = \min_z \ell_N(x_N) + \sum_{k=0}^{N-1} \ell(x_k, u_k) \quad (1a)$$

$$\text{s.t. } x_{k+1} = Ax_k + Bu_k \quad (1b)$$

$$C_x x_k + C_u u_k \leq c \quad (1c)$$

$$k = 0, \dots, N-1$$

$$C_N x_N \leq c_N \quad (1d)$$

$$x_0 = x \quad (1e)$$

where N is the prediction horizon; $x \in \mathbb{R}^m$ is the current state vector of the controlled system; $u_k \in \mathbb{R}^{n_u}$ is the vector of manipulated variables at prediction time k , $k = 0, \dots, N-1$; $z \triangleq$

$[u'_0 \dots u'_{N-1}]' \in \mathbb{R}^n$, $n \triangleq n_u N$, is the vector of decision variables to be optimized;

$$\ell(x, u) = \frac{1}{2}x'Qx + u'Ru \quad (2a)$$

$$\ell_N(x) = \frac{1}{2}x'Px \quad (2b)$$

are the stage cost and terminal cost, respectively; Q , P are symmetric and positive semidefinite matrices; and R is a symmetric and positive definite matrix.

Let $n_c \in \mathbb{N}$ be the number of constraints imposed at prediction time $k = 0, \dots, N-1$, namely, $C_x \in \mathbb{R}^{n_c \times m}$, $C_u \in \mathbb{R}^{n_c \times n_u}$, and $c \in \mathbb{R}^{n_c}$, and let n_N be the number of terminal constraints, namely, $C_N \in \mathbb{R}^{n_N \times m}$ and $c_N \in \mathbb{R}^{n_N}$. The total number q of linear inequality constraints imposed in the MPC problem formulation (1) is $q = Nn_c + n_N$.

By eliminating the states $x_k = A^k x + \sum_{j=0}^{k-1} A^j B u_{k-1-j}$ from problem (1), the optimal control problem (1) can be expressed as the convex quadratic program (QP):

$$V^*(x) \triangleq \min_z \quad \frac{1}{2}z'H z + x'F'z + \frac{1}{2}x'Yx \quad (3a)$$

$$\text{s.t.} \quad Gz \leq W + Sx \quad (3b)$$

where $H = H' \in \mathbb{R}^{n \times n}$ is the Hessian matrix; $F \in \mathbb{R}^{n \times m}$ defines the linear term of the cost function; $Y \in \mathbb{R}^{m \times m}$ has no influence on the optimizer, as it only affects the optimal value of (3a); and the matrices $G \in \mathbb{R}^{q \times n}$, $S \in \mathbb{R}^{q \times m}$, $W \in \mathbb{R}^q$ define in a compact form the constraints imposed in (1). Because of the assumptions made on the weight matrices Q , R , and P , matrix H is positive definite, and matrix $\begin{bmatrix} H & F' \\ F & Y \end{bmatrix}$ is positive semidefinite.

The MPC control law is defined by setting

$$u(x) = [I \ 0 \ \dots \ 0]z(x) \quad (4)$$

where $z(x)$ is the optimizer of the QP problem (3) for the current value of x and I is the identity matrix of dimension $n_u \times n_u$.

Multiparametric Solution

Rather than using a numerical QP solver online to compute the optimizer $z(x)$ of (3) for each given current state vector x , the basic idea of explicit MPC is to pre-solve the QP off-line for the entire set of states x (or for a convex polyhedral subset $X \subseteq \mathbb{R}^m$ of interest) to get the optimizer function z , and therefore the MPC control law u , explicitly as a function of x .

The main tool to get such an explicit solution is *multiparametric quadratic programming* (mpQP). For mpQP problems of the form (3), Bemporad et al. (2002b) proved that the optimizer function $z^* : X_f \mapsto \mathbb{R}^n$ is piecewise affine and continuous over the set X_f of parameters x for which the problem is feasible (X_f is a polyhedral set, possibly $X_f = X$) and that the value function $V^* : X_f \mapsto \mathbb{R}$ associating with every $x \in X_f$ the corresponding optimal value of (3) is continuous, convex, and piecewise quadratic.

An immediate corollary is that the explicit version of the MPC control law u in (4), being the first n_u components of vector $z(x)$, is also a continuous and piecewise-affine state-feedback law defined over a partition of the set X_f of states into M polyhedral cells:

$$u(x) = \begin{cases} F_1 x + g_1 & \text{if } H_1 x \leq K_1 \\ \vdots & \vdots \\ F_M x + g_M & \text{if } H_M x \leq K_M \end{cases} \quad (5)$$

An example of such a partition is depicted in Fig. 1. The explicit representation (5) has mapped the MPC law (4) into a lookup table of linear gains, meaning that for each given x , the values computed by solving the QP (3) online and those obtained by evaluating (5) are exactly the same.

Multiparametric QP Algorithms

A few algorithms have been proposed in the literature to solve the mpQP problem (3). All of them construct the solution by exploiting the Karush-Kuhn-Tucker (KKT) conditions for optimality:

$$Hz + Fx + G'\lambda = 0 \quad (6a)$$

Explicit Model Predictive Control, Fig. 1 Explicit MPC solution for the double integrator example

E

$$\lambda_i(G^i z - W^i - S^i x) = 0, \forall i = 1, \dots, q \quad (6b)$$

$$Gz \leq W + Sx \quad (6c)$$

$$\lambda \geq 0 \quad (6d)$$

$$\hat{\lambda}(x) = 0 \quad (8b)$$

where $\lambda \in \mathbb{R}^q$ is the vector of Lagrange multipliers. For the strictly convex QP (3), conditions (6) are necessary and sufficient to characterize optimality.

An mpQP algorithm starts by fixing an arbitrary starting parameter vector $x_0 \in \mathbb{R}^m$ (e.g., the origin $x_0 = 0$), solving the QP (3) to get the optimal solution $z(x_0)$, and identifying the subset

$$\tilde{G}z(x) = \tilde{S}x + \tilde{W} \quad (7a)$$

of all constraints (6c) that are active at $z(x_0)$ and the remaining inactive constraints:

$$\hat{G}z(x) \leq \hat{S}x + \hat{W} \quad (7b)$$

Correspondingly, in view of the complementarity condition (6b), the vector of Lagrange multipliers is split into two subvectors:

$$\tilde{\lambda}(x) \geq 0 \quad (8a)$$

We assume for simplicity that the rows of $\tilde{G}$ are linearly independent. From (6a), we have the relation

$$z(x) = -H^{-1}(Fx + \tilde{G}'\tilde{\lambda}(x)) \quad (9)$$

that, when substituted into (7a), provides

$$\tilde{\lambda}(x) = -\tilde{M}(\tilde{W} + (\tilde{S} + \tilde{G}H^{-1}F)x) \quad (10)$$

where $\tilde{M} = \tilde{G}'(\tilde{G}H^{-1}\tilde{G}')^{-1}$ and, by substitution in (9),

$$z(x) = H^{-1}(\tilde{M}\tilde{W} + \tilde{M}(\tilde{S} + \tilde{G}H^{-1}F)x - Fx) \quad (11)$$

The solution $z(x)$ provided by (11) is the correct one for all vectors x such that the chosen combination of active constraints remains optimal. Such all vectors x are identified by imposing constraints (7b) and (8a) on $z(x)$ and $\tilde{\lambda}(x)$, respectively, that leads to constructing the polyhedral set (“critical region”):

$$CR_0 = \{x \in \mathbb{R}^n : \tilde{\lambda}(x) \geq 0, \hat{G}z(x) \leq \hat{W} + \hat{S}x\} \quad (12)$$

Different mpQP solvers were proposed to cover the rest $X \setminus CR_0$ of the parameter set with other critical regions corresponding to new combinations of active constraints. The most efficient methods exploit the so-called “facet-to-facet” property of the multiparametric solution (Spjøtvold et al. 2006) to identify neighboring regions as in Tøndel et al. (2003a), Baotić (2002), and Bemporad (2015). Alternative methods were proposed in Jones and Morari (2006), based on looking at (6) as a multiparametric linear complementarity problem, in Patrinos and Sarimveis (2010), which provides algorithms for determining all neighboring regions even in the case the facet-to-facet property does not hold, and in Gupta et al. (2011) based on the implicit enumeration of active constraint combinations.

All methods handle the case of *degeneracy*, which may happen for some combinations of active constraints that are linearly dependent, that is, the associated matrix $\tilde{G}$ has no full row rank (in this case, $\tilde{\lambda}(x)$ may not be uniquely defined).

Extensions

The explicit approach described earlier can be extended to the following MPC setting:

$$\min_{z, \epsilon} \sum_{k=0}^{N-1} \frac{1}{2} (y_k - \mathbf{r}_k)' Q_y (y_k - \mathbf{r}_k) + \frac{1}{2} \Delta u_k' R \Delta u_k + (u_k - \mathbf{u}_k^r)' R (u_k - \mathbf{u}_k^r)' + \rho \epsilon^2 \quad (13a)$$

$$\text{s.t. } x_{k+1} = Ax_k + Bu_k + B_v \mathbf{v}_k \quad (13b)$$

$$y_k = Cx_k + Du_k + D_v \mathbf{v}_k \quad (13c)$$

$$u_k = u_{k-1} + \Delta u_k, \quad k = 0, \dots, N-1 \quad (13d)$$

$$\Delta u_k = 0, \quad k = N_u, \dots, N-1 \quad (13e)$$

$$\mathbf{u}_{\min}^k \leq u_k \leq \mathbf{u}_{\max}^k, \quad k = 0, \dots, N_u - 1 \quad (13f)$$

$$\Delta \mathbf{u}_{\min}^k \leq \Delta u_k \leq \Delta \mathbf{u}_{\max}^k, \quad k = 0, \dots, N_u - 1 \quad (13g)$$

$$\mathbf{y}_{\min}^k - \epsilon V_{\min} \leq y_k \leq \mathbf{y}_{\max}^k + \epsilon V_{\max} \quad (13h)$$

$$k = 0, \dots, N_c - 1$$

where R_Δ is a symmetric and positive definite matrix; matrices Q_y and R are symmetric and positive semidefinite; $\mathbf{v}_k$ is a vector of measured disturbances; y_k is the output vector; $\mathbf{r}_k$ its corresponding reference to be tracked; Δu_k is the vector of input increments; $\mathbf{u}_k^r$ is the input reference; $\mathbf{u}_{\min}^k, \mathbf{u}_{\max}^k, \Delta \mathbf{u}_{\min}^k, \Delta \mathbf{u}_{\max}^k, \mathbf{y}_{\min}^k, \mathbf{y}_{\max}^k$ are bounds; and N, N_u, N_c are, respectively, the prediction, control, and constraint horizons. The extra variable ϵ is introduced to soften output constraints, penalized by the (usually large) weight ρ_ϵ in the cost function (13a).

Everything marked in boldface in (13), together with the command input u_{-1} applied at the previous sampling step and the current state x , can be treated as a parameter with respect to which to solve the mpQP problem and obtain the explicit form of the MPC controller. For example, for a tracking problem with no anticipative action ($\mathbf{r}_k \equiv r_0, \forall k = 0, \dots, N-1$), no measured disturbance, and fixed upper and lower bounds, the explicit solution is a continuous piecewise-affine function of the parameter vector $\begin{bmatrix} x \\ r_0 \\ u_{-1} \end{bmatrix}$. Note that prediction models and/or weight matrices in (13) cannot be treated as parameters to maintain the mpQP formulation (3).

Linear MPC Based on Convex Piecewise-Affine Costs

A similar setting can be repeated for MPC problems based on linear prediction models and convex piecewise-affine costs, such as 1- and ∞ -norms. In this case, the MPC problem is mapped into a multiparametric linear programming (mpLP) problem, whose solution is again continuous and piecewise-affine with respect to the vector of parameters. For details, see Bemporad et al. (2002a).

Robust MPC

Explicit solutions to min-max MPC problems that provide robustness with respect to additive and/or multiplicative unknown-but-bounded uncertainty were proposed in Bemporad et al. (2003), based on a combination of mpLP and dynamic programming. Again the solution is piecewise affine with respect to the state vector.

Hybrid MPC

An MPC formulation based on convex piecewise-affine costs (like 1- or ∞ -norms) and linear hybrid dynamics expressed in mixed-logical dynamical (MLD) form can be solved explicitly by treating the optimization problem associated with MPC as a multiparametric mixed integer linear programming (mpMILP) problem. The solution is still piecewise affine but may be discontinuous, due to the presence of binary variables (Bemporad et al. 2000). A better approach based on dynamic programming combined with mpLP (or mpQP) was proposed in Borrelli et al. (2005) for hybrid systems in piecewise-affine (PWA) dynamical form and linear (or quadratic) costs. For explicit hybrid MPC based on quadratic costs, the issue of possible partition overlaps is solved in Fuchs et al. (2015).

Applicability of Explicit MPC

Complexity of the Solution

The complexity of the solution is given by the number M of regions that form the explicit solution (5), dictating the amount of memory to store the parametric solution (F_i , G_i , H_i , K_i , $i = 1, \dots, M$) and the worst-case execution time required to compute $F_i x + G_i$ once the problem of identifying the index i of the region $\{x : H_i x \leq K_i\}$ containing the current state x is solved (which usually takes most of the time). The latter is called the “point location problem,” and a few methods have been proposed to solve the problem more efficiently than searching linearly through the list of regions (see, e.g., the tree-based approach of Tøndel et al. 2003b).

An upper bound to M is 2^q , which is the number of all possible combinations of active constraints. In practice, M is much smaller than 2^q , as most combinations are never active at optimality for any of the vectors x (e.g., lower and upper limits on an actuation signal cannot be active at the same time, unless they coincide). Moreover, regions in which the first n_u component of the multiparametric solution $z(x)$ is the same can be joined together, provided that their union is a convex set (an optimal merging algorithm was proposed by Geyer et al. (2008) to get a minimal number M of partitions). Nonetheless, the complexity of the explicit MPC law typically grows exponentially with the number q of constraints. The number m of parameters is less critical and mainly affects the number of elements to be stored in memory (i.e., the number of columns of matrices F_i , H_i). The number n of free variables also affects the number M of regions, mainly because they are usually upper and lower bounded.

Computer-Aided Tools

The Model Predictive Control Toolbox (Bemporad et al. 2014) offers functions for designing explicit MPC controllers in MATLAB since 2014, implementing the algorithm described (Bemporad 2015). Other tools exist such as the Hybrid Toolbox (Bemporad 2003) and the Multi-Parametric Toolbox (Kvasnica et al. 2006).

Summary and Future Directions

Explicit MPC is a powerful tool to convert an MPC design into an equivalent control law that can be implemented as a lookup table of linear gains. Whether explicit MPC is preferable to online QP depends on available CPU time, data memory, program memory, and other practical considerations. In order to answer this question, Cimini and Bemporad (2017) analyzed the behavior of a state-of-the-art dual active set method for QP in a parametric way, finding out that the number of iterations to solve the QP online is a piecewise constant function of the

parameter vector. They precisely quantify how many flops the online QP solver takes in the worst case, so that the corresponding CPU time, as well as memory footprint, can be exactly compared with explicit MPC. Although suboptimal explicit MPC methods have been proposed for reducing the complexity of the control law, still the multiparametric approach remains convenient for relatively small problems (say one or two command inputs, short control and constraint horizons, up to ten states). For larger-size problems and/or time-varying prediction models, online QP solution methods tailored to embedded MPC are usually preferable.

Recommended Reading

For getting started in explicit MPC, we recommend reading the paper by Bemporad et al. (2002b) and the survey paper by Alessio and Bemporad (2009). Hands-on experience using one of the MATLAB tools listed above is also useful for fully appreciating the potentials and limitations of explicit MPC. For understanding how to program a good multiparametric QP solver, the reader is recommended to take one of the approaches described in Tøndel et al. (2003a), Spjøtvold et al. (2006), Bemporad (2015), Patrinos and Sarimveis (2010), or Jones and Morari (2006).

Extended Kalman Filters

Frederick E. Daum
Raytheon Company, Woburn, MA, USA

Abstract

The extended Kalman filter (EKF) is the most popular estimation algorithm in practical applications. It is based on a linear approximation to the Kalman filter theory. There are thousands of variations of the basic EKF design, which are intended to mitigate the effects of nonlinearities, non-Gaussian errors, ill-conditioning of the covariance matrix and uncertainty in the parameters of the problem.

Keywords

Estimation · Nonlinear filters

Synonyms

[EKF](#)

The extended Kalman filter (EKF) is by far the most popular nonlinear filter in practical engineering applications. It uses a linear approximation to the nonlinear dynamics and measurements and exploits the Kalman filter theory, which is optimal for linear and Gaussian problems; Gelb (1974) is the most accessible but thorough book on the EKF. The real-time computational complexity of the EKF is rather modest; for example, one can run an EKF with high-dimensional state vectors (d = several hundreds) in real time on a single microprocessor chip. The computational complexity of the EKF scales as the cube of the dimension of the state vector (d) being estimated. The EKF often gives good estimation accuracy for practical nonlinear problems, although the EKF accuracy can be very poor for difficult nonlinear non-Gaussian problems. There are many different variations of EKF algorithms, most of which are intended to improve estimation accuracy. In particular, the following types of EKFs are common in engineering practice: (1) second-order Taylor series expansion of the nonlinear functions, (2) iterated measurement updates that recompute the point at which the first order Taylor series is evaluated for a given measurement, (3) second-order iterated (i.e., combination of items 1 and 2), (4) special coordinate systems (e.g., Cartesian, polar or spherical, modified polar or spherical, principal axes of the covariance matrix ellipse, hybrid coordinates, quaternions rather than Euler angles, etc.), (5) preferred order of processing sequential scalar measurement updates, (6) decoupled or partially decoupled or quasi-decoupled covariance matrices, and many more variations. In fact, there is no such thing as “the” EKF, but rather there are thousands of different versions of the EKF. There are also many different versions of the Kalman filter itself, and all of these can be used to design EKFs as well. For example, there are many different equations to update the Kalman filter error covariance matrices with the intent of mitigating ill-conditioning and improving robustness, including (1) square-root factorization of the covariance matrix, (2) information matrix update, (3) square-root information update, (4) Joseph’s robust version

of the covariance matrix update, (5) at least three distinct algebraic versions of the covariance matrix update, as well as hybrids of the above.

Many of the good features of the Kalman filter are also enjoyed by the EKF, but unfortunately not all. For example, we have a very good theory of stability for the Kalman filter, but there is no theory that guarantees that an EKF will be stable in practical applications. The only method to check whether the EKF is stable is to run Monte Carlo simulations that cover the relevant regions in state space with the relevant measurement parameters (e.g., data rate and measurement accuracy). Secondly, the Kalman filter computes the theoretical error covariance matrix, but there is no guarantee that the error covariance matrix computed by the EKF approximates the actual filter errors, but rather the EKF covariance matrix could be optimistic by orders of magnitude in real applications. Third, the numerical values of the process noise covariance matrix can be computed theoretically for the Kalman filter, but there is no guarantee that these will work well for the EKF, but rather engineers typically tune the process noise covariance matrix using Monte Carlo simulations or else use a heuristic adaptive process (e.g., IMM). All of these shortcomings of the EKF compared with the Kalman filter theory are due to a myriad of practical issues, including (1) nonlinearities in the dynamics or measurements, (2) non-Gaussian measurement errors, (3) unmodeled measurement error sources (e.g., residual sensor bias), (4) unmodeled errors in the dynamics, (5) data association errors, (6) unresolved measurement data, (7) ill-conditioning of the covariance matrix, etc. The actual estimation accuracy of an EKF can only be gauged by Monte Carlo simulations over the relevant parameter space.

The actual performance of an EKF can depend crucially on the specific coordinate system that is used to represent the state vector. This is extremely well known in practical engineering applications (e.g., see Mehra 1971; Stallard 1991; Miller 1982; Markley 2007; Daum 1983; Schuster 1993). Intuitively, this is because the dynamics and measurement equations can be exactly linear in one coordinate system but not

another; this is very easy to see; start with dynamics and measurements that are exactly linear in Cartesian coordinates and transform to polar coordinates and we will get highly nonlinear equations. Likewise, we can have approximately linear dynamics and measurements in a specific coordinate system but highly nonlinear equations in another coordinate system. But in theory, the optimal estimation accuracy does not depend on the coordinate system. Moreover, in math and physics, coordinate-free methods are preferred, owing to their greater generality and simplicity and power. The physics does not depend on the specific coordinate system; this is essentially a definition of what “physics” means, and it has resulted in great progress in physics over the last few hundred years (e.g., general relativity, gauge invariance in quantum field theory, Lorentz invariance in special relativity, as well as a host of conservation laws in classical mechanics that are explained by Noether’s theorem which relates invariance to conserved quantities). Similarly in math, coordinate-free methods have been the royal road to progress over the last 100 years but not so for practical engineering of EKFs, because EKFs are approximations rather than being exact, and the accuracy of the EKF approximation depends crucially on the specific coordinate system used. Moreover, the effect of ill-conditioning of the covariance matrices in EKFs depends crucially on the specific coordinate system used in the computer; for example, if we could compute the EKF in principal coordinates, then the covariance matrices would be diagonal, and there would be no effect of ill-conditioning, despite enormous condition numbers of the covariance matrices. Surprisingly, these two simple points about coordinate systems are still not well understood by many researchers in nonlinear filtering.

Extremum Seeking Control

Miroslav Krstic
Department of Mechanical and Aerospace
Engineering, University of California,
San Diego, La Jolla, CA, USA

Abstract

Extremum seeking (ES) is a method for real-time non-model-based optimization. Though ES was invented in 1922, the “turn of the twenty-first century” has been its golden age, both in terms of the development of theory and in terms of its adoption in industry and in fields outside of control engineering. This entry overviews basic gradient- and Newton-based versions of extremum seeking with periodic and stochastic perturbation signals.

Keywords

Extremum seeking · Averaging · Optimization · Stability

Introduction

Many versions of extremum seeking exist, with various approaches to their stability study (Krstic and Wang 2000; Tan et al. 2006; Liu and Krstic 2012). The most common version employs perturbation signals for the purpose of estimating the gradient of the unknown map that is being optimized. To understand the basic idea of extremum seeking, it is best to first consider the case of a static single-input map of the quadratic form, as shown in Fig. 1.

The Basic Idea of Extremum Seeking

Three different thetas appear in Fig. 1: θ^* is the unknown optimizer of the map, $\hat{\theta}(t)$ is the real-time estimate of θ^* , and $\theta(t)$ is the actual input into the map. The actual input $\theta(t)$ is based on the estimate $\hat{\theta}(t)$ but is perturbed by the signal $a \sin(\omega t)$ for the purpose of estimating the

Extremum Seeking Control, Fig. 1 The simplest perturbation-based extremum seeking scheme for a quadratic single-input map $f(\theta) = f^* + \frac{f''}{2} (\theta - \theta^*)^2$, where f^* , f'' , θ^* are all unknown. The user has to only know the sign of f'' , namely, whether the quadratic map has a maximum or a minimum, and has to choose the adaptation gain k such that $\text{sgn} k = -\text{sgn} f''$. The user has to also choose the frequency ω as relatively large compared to a , k , and f''

unknown gradient $f'' \cdot (\theta - \theta^*)$ of the map $f(\theta)$. The sinusoid is only one choice for a perturbation signal – many other perturbations, from square waves to stochastic noise, can be used in lieu of sinusoids, provided they are of zero mean. The estimate $\hat{\theta}(t)$ is generated with the integrator k/s with the adaptation gain k controlling the speed of estimation.

The ES algorithm is successful if the error between the estimate $\hat{\theta}(t)$ and the unknown θ^* , namely, the signal

$$\tilde{\theta}(t) = \hat{\theta}(t) - \theta^* \quad (1)$$

can be made to converge to any prescribed neighborhood of zero. Based on Fig. 1, the estimate is governed by the differential equation $\dot{\hat{\theta}} = k \sin(\omega t) f(\theta)$, which means that the estimation error is governed by

$$\frac{d\tilde{\theta}}{dt} = ka \sin(\omega t) \left[f^* + \frac{f''}{2} \left(\tilde{\theta} + a \sin(\omega t) \right)^2 \right] \quad (2)$$

Expanding the right-hand side one obtains

$$\begin{aligned} \frac{d\tilde{\theta}(t)}{dt} = & ka f^* \underbrace{\sin(\omega t)}_{\text{mean}=0} + ka^3 \frac{f''}{2} \underbrace{\sin^3(\omega t)}_{\text{mean}=0} \\ & + ka \frac{f''}{2} \underbrace{\sin(\omega t)}_{\text{fast, mean}=0} \underbrace{\tilde{\theta}(t)^2}_{\text{slow}} \\ & + ka^2 f'' \underbrace{\sin^2(\omega t)}_{\text{fast, mean}=1/2} \underbrace{\tilde{\theta}(t)}_{\text{slow}}. \end{aligned} \quad (3)$$

A theoretically rigorous time-averaging procedure allows to replace the above sinusoidal signals by their means, yielding the “average system”

$$\frac{d\tilde{\theta}_{\text{ave}}}{dt} = \frac{\overbrace{k f'' a^2}^{<0}}{2} \tilde{\theta}_{\text{ave}}, \quad (4)$$

which is exponentially stable. The averaging theory guarantees that there exists sufficiently large ω such that, if the initial estimate $\hat{\theta}(0)$ is

sufficiently close to the unknown θ^* ,

$$\begin{aligned} |\theta(t) - \theta^*| \leq & |\theta(0) - \theta^*| e^{\frac{k f'' a^2}{2} t} \\ & + O\left(\frac{1}{\omega}\right) + a, \quad \forall t \geq 0. \end{aligned} \quad (5)$$

For the user, the inequality (5) guarantees that, if a is chosen small and ω is chosen large, the input $\theta(t)$ exponentially converges to a small interval around the unknown θ^* and, consequently, the output $f(\theta(t))$ converges to the vicinity of the optimal output f^* .

ES for Multivariable Static Maps

For static maps, ES extends in a straightforward manner from the single-input case shown in Fig. 1 to the multi-input case shown in Fig. 2.

The algorithm measures the scalar signal $y(t) = Q(\theta(t))$, where $Q(\cdot)$ is an unknown map whose input is the vector $\theta = [\theta_1, \theta_2, \dots, \theta_n]^T$. The gradient is estimated with the help of the signals

$$S(t) = \begin{bmatrix} a_1 \sin(\omega_1 t) & \cdots & a_n \sin(\omega_n t) \end{bmatrix}^T \quad (6)$$

$$M(t) = \begin{bmatrix} \frac{2}{a_1} \sin(\omega_1 t) & \cdots & \frac{2}{a_n} \sin(\omega_n t) \end{bmatrix}^T \quad (7)$$

with nonzero perturbation amplitudes a_i and with a gain matrix K that is diagonal. To guarantee convergence, the user should choose $\omega_i \neq \omega_j$. This is a key condition that differentiates the multi-input case from the single-input case. In addition, for simplicity in the convergence analysis, the user should choose ω_i/ω_j as rational and $\omega_i + \omega_j \neq \omega_k$ for distinct i, j , and k .

If the unknown map is quadratic, namely, $Q(\theta) = Q^* + \frac{1}{2}(\theta - \theta^*)^T H(\theta - \theta^*)$, the averaged system is

$$\dot{\tilde{\theta}}_{\text{ave}} = K H \tilde{\theta}_{\text{ave}}, \quad H = \text{Hessian}. \quad (8)$$

If, for example, the map $Q(\cdot)$ has a maximum that is locally quadratic (which implies $H = H^T < 0$), and if the user chooses the elements of the diagonal gain matrix K as positive, the ES algorithm is guaranteed to be locally convergent. However, the convergence rate depends on

the unknown Hessian H . This weakness of the gradient-based ES algorithm is removed with the Newton-based ES algorithm.

A stochastic version of the algorithm in Fig. 2 also exists, in which $S(t)$ and $M(t)$ are replaced by

$$S(\eta(t)) = [a_1 \sin(\eta_1(t)), \dots, a_n \sin(\eta_n(t))]^T, \quad (9)$$

$$M(\eta(t)) = \left[\frac{2}{a_1(1 - e^{-q_1^2})} \sin(\eta_1(t)), \dots, \frac{2}{a_n(1 - e^{-q_n^2})} \sin(\eta_n(t)) \right]^T \quad (10)$$

where $\eta_i = \frac{q_i \sqrt{\varepsilon_i}}{\varepsilon_i s + 1} [\dot{W}_i]$ and $\dot{W}_i$ are independent unity-intensity white noise processes.

ES for Dynamic Systems

ES extends in a relatively straightforward manner from static maps to dynamic systems, provided the dynamics are stable and the algorithm's parameters are chosen so that the algorithm's dynamics are slower than those of the plant. The algorithm is shown in Fig. 3.

The technical conditions for convergence in the presence of dynamics are that the equilibria $x = l(\theta)$ of the system $\dot{x} = f(x, \alpha(x, \theta))$, where $\alpha(x, \theta)$ is the control law of an internal feedback loop, are locally exponentially stable uniformly in θ and that, given the output map $y = h(x)$, there exists at least one $\theta^* \in \mathbb{R}^n$

such that $\frac{\partial}{\partial \theta}(h \circ l)(\theta^*) = 0$ and $\frac{\partial^2}{\partial \theta^2}(h \circ l)(\theta^*) = H < 0$, $H = H^T$.

The stability analysis in the presence of dynamics employs both averaging and singular perturbations, in a specific order. The design guidelines for the selection of the algorithm's parameters follow the analysis, ensuring that the plant's dynamics are on a fast time scale, the perturbations are on a medium time scale, and the ES algorithm is on a slow time scale. Such a three-time-scale separation is achieved by the following selection process for the algorithm's parameters.

First, the user starts from some approximate knowledge of the time constants of the plant, even though the plant's model is largely uncertain. Second, the user selects the perturbation frequency whose period is relatively large compared to the time constants of the plant. That ensures that the perturbation is on a slower time scale than the plant, letting the plant dynamics “nearly settle” after any significant change in $\hat{\theta}(t)$. Finally, i.e., the parameters of the algorithm, including the gain K , perturbation amplitude a , and the filter poles ω_h and ω_l , are chosen by the user to be relatively small relative to the perturbation frequency ω . This ensures that the algorithm evolves on a slower time scale than the perturbation frequency. In summary, the overall system evolves on three time scales.

On the analysis side, the slowness of the perturbation allows the applicability of a singular perturbation argument in the analysis, treating the

Extremum Seeking Control, Fig. 2 Extremum seeking algorithm for a multivariable map $y = Q(\theta)$, where θ is the input vector $\theta = [\theta_1, \theta_2, \dots, \theta_n]^T$. The algorithm employs the additive perturbation vector signal $S(t)$ given in (6) and the multiplicative demodulation vector signal $M(t)$ given in (7)

plant dynamics as “instantaneous.” The slowness of the algorithm relative to its perturbation ω allows the applicability of an averaging argument in the analysis of the reduced system with the plant dynamics treated as instantaneous.

$$N_{ii}(t) = \frac{16}{a_i^2} \left(\sin^2(\omega_i t) - \frac{1}{2} \right),$$

$$N_{ij}(t) = \frac{4}{a_i a_j} \sin(\omega_i t) \sin(\omega_j t) \quad (11)$$

For a quadratic map, the averaged system in error variables $\tilde{\theta} = \hat{\theta} - \theta^*$, $\tilde{\Gamma} = \Gamma - H^{-1}$ is

Newton ES Algorithm for Static Map

A Newton version of the ES algorithm, shown in Fig. 4, ensures that the convergence rate be user-assignable, rather than being dependent on the unknown Hessian of the map.

The elements of the demodulating matrix $N(t)$ for generating the estimate of the Hessian are given by

$$\begin{aligned} \frac{d\tilde{\theta}^{\text{ave}}}{dt} &= -K\tilde{\theta}^{\text{ave}} - \underbrace{K\tilde{\Gamma}^{\text{ave}}H\tilde{\theta}^{\text{ave}}}_{\text{quadratic}}, \\ \frac{d\tilde{\Gamma}^{\text{ave}}}{dt} &= -\omega_r\tilde{\Gamma}^{\text{ave}} - \omega_r\tilde{\Gamma}^{\text{ave}}\underbrace{H\tilde{\Gamma}^{\text{ave}}}_{\text{quadratic}}. \end{aligned} \quad (12)$$

Extremum Seeking Control, Fig. 3 The ES algorithm in the presence of dynamics with an equilibrium map $\theta \mapsto y$ that satisfies the same conditions as in the static case. If the dynamics are stable and the user employs parameters in the ES algorithm that make the algorithm dynamics

slower than the dynamics of the plant, convergence is guaranteed (at least locally). The two filters are useful in the implementation to reduce the adverse effect of the perturbation signals on asymptotic performance but are not needed in the stability analysis

Extremum Seeking Control, Fig. 4 A Newton-based ES algorithm for a static map. The multiplicative excitation $N(t)$ helps generate the estimate of Hessian $\frac{\partial^2 Q(\theta)}{\partial \theta^2}$ as $\hat{H}(t) = N(t)y(t)$. The Riccati matrix differential equation

$\dot{\Gamma}(t)$ generates an estimate of the Hessian's *inverse* matrix, avoiding matrix inversions of Hessian estimates that may be singular during the transient

Since the eigenvalues are determined by K and ω_r and are therefore independent of the unknown H , the (local) convergence rate is user-assignable.

Further Reading on Extremum Seeking

Since the publication of the first proof of stability of extremum seeking (Krstic and Wang 2000), thousands of papers have been published on this topic, presenting further theoretical developments and applications of ES. A proof that expands the validity of extremum seeking from local to global stability was published in Tan et al. (2006). The references Liu and Krstic (2010a, 2012) present stochastic versions of the algorithms in this entry, where the sinusoids are replaced by filtered white noise perturbation signals.

Among the natural applications of extremum seeking is the maximization of efficiency of renewable energy systems, notably, maximum power point tracking (MPPT) for photovoltaic (Ghaffari et al. 2014a) and wind (Ghaffari et al. 2014b) energy conversion.

“Source seeking” with autonomous vehicles has been one of the major applications of real-time optimization for dynamic systems. The first result in seeking the location of a signal source with a nonholonomic vehicle is Cochran and Krstic (2009), subsequently also achieved with stochastic perturbations and averaging (Liu and Krstic 2010b), whereas a more general problem of following any level set other than the trivial level set, at the extremum, is shown to be

solvable without perturbation-based extremum seeking but, instead, with an elegant use of PI feedback (Baronov and Baillieul 2011).

Facility Control and Optimization Problems in Data Centers

Zhikui Wang
Cupertino, CA, USA

Abstract

Facility design and operation of data centers evolved through a few generations in the last decade, resulting in significant improvement of energy efficiency and operation reliability. The real-time control and optimization problems are challenging because of the heterogeneous architectures, nonlinearity of the systems under control, spatial and temporal variability of the dynamics, and tight coupling of the subsystems. This entry provides a brief introduction of the challenges through discussion about one server enclosure system and one typical data center cooling architecture.

Keywords

Data center facility · Thermal dynamics · Flow dynamics · Optimal control

Introduction

Data centers are special buildings. They run the critical Information and Communication Technology (ICT) infrastructure that hosts the Internet or enterprise applications and serves the operation of governments, schools, enterprises, business, and industries. A typical data center contains one or more computer or machine rooms, hosting the ICT equipment including computing, networking, and storage hardware, together with the power and cooling facility. It is a complicated system running 24×7 , for which reliability is of the first concern. High reliability is first considered through redundant designs in power, cooling, and ICT architectures. During the operation time, feedback control is applied to maintain the stability of the systems upon external disturbance, e.g., environmental changes, failures of equipment, or resource demand changes from the ICT applications. Energy efficiency is critical due to the cost and emerging environmental concerns. It has been improved significantly in the past decade with adoption of new architectures, systems, and products from chips, ICT systems to power/cooling facility (Barroso et al. 2018). Dynamic control and optimization also play important roles to reduce energy consumption while maintaining the operation performance.

Modeling and Control of a Computer

A data center runs like a computer (Barroso et al. 2018). The main subsystems, including power, cooling, and computing, are tightly coupled. The interaction among these subsystems involves complicated thermal and fluid dynamics. Figure 1 illustrates one example of a computer, an enclosure with 16 blade servers in the front cooled by ten fans in the back. The fans pull air flows through the blades toward the back of the enclosure. Building numerical models are viable for such a small-scale system with appropriate approximation and simplification (Wang et al. 2009).

Based on energy balance, the change rate of the CPU temperature is approximately the sum of the rate at which heat is generated within the CPU device and the rate at which heat is transferred from the CPU to the ambient air flow, as represented below for the blade j .

$$C_1 \frac{dT_{CPU,j}}{dt} = \frac{C_2}{R_j} (T_{inlet,j} - T_{CPU,j}) + Q_j, \quad (1)$$

where C_1 and C_2 are constants related to the fluid properties of air, CPU package geometry, and material properties and T_{inlet} is the temperature of the cold air. Q is the heat transferred from the processor. It is not measurable but can be represented by the CPU power consumption, P_{CPU} ,

Facility Control and Optimization Problems in Data Centers, Fig. 1 A blade server enclosure (Wang et al. 2009)

which is usually modeled as a linear function of its utilization $Util$ with a bias of the idle power $P_{CPU, idle}$: $P_{CPU,j} = g_{CPU,j} * Util_j + P_{CPU,j, idle}$. R_j is the lumped thermal resistance between CPU and the cold air. Approximately,

$$R_j = \frac{C_3}{\dot{V}_j^{n_R}} + C_4, \quad \text{for blade } j, \quad (2)$$

where C_3 and C_4 are constants related to the fluid and material properties of the air, the CPU package, and the heatsink. The parameter n_R defines the shape of the thermal resistance curve as a function of the air flow rate $\dot{V}$.

On the flow dynamic side, the air flow through one blade may come from multiple fans, and the rate of the air flow generated by each fan $\dot{V}$ is about proportional to the fan speed FS . That is,

$$\dot{V}_j = \sum_i \eta_{ij} \times FS_i, \quad \text{for blade } j, \quad (3)$$

where η_{ij} is the correlation index between the speed of fan i and the air flow rate in blade j .

The models (1)–(3) could have been oversimplified but are still identifiable through system identification experiments (Wang et al. 2009). They capture the interaction among power, cooling, and computing workload in the enclosure, representing the non-uniform spatial and temporal cooling efficiency of the fans. The models imply a few ways to improve both efficiency and reliability. Below are a few examples.

- The total power consumption of the fans may be optimized because their capacity is shared by the blades. For instance, four fans running at 25% speed can provide the same volume of air flow as two fans running at 50% speed; however, the total fan power is reduced to 25% since the fan power is about a cubic function of the speed. An optimal fan controller is viable with the models identified (Wang et al. 2009).
- Moving workload around to take advantage of the spatial or temporal variance of cooling efficiency may improve the overall efficiency. It is usually formulated as a constrained

mixed-integer optimization problem (Tolia et al. 2009).

- Reliability can be improved because of sharing of the cooling capacity. Upon failures of one or more fans, a feedback controller can still drive the other fans to complement the capacity loss due to the failures.

Data Center Level Modeling and Control

Figure 2 shows a traditional raised-floor cooling architecture inside a data center. The ICT equipment is housed in standard racks sitting atop a raised floor. The floor creates a plenum that is pressurized with cold air from CRAC (Computer Room Air Conditioning) units. Cold air is delivered to the ICT equipment via perforated or grated vent tiles in the floor. ICT equipment is typically designed to move air from the front of the rack to the back. Racks are arranged to form hot aisles and cold aisles to reduce the likelihood of equipment ingesting exhaust hot air from nearby racks. The exhaust air returns to the CRAC units either through the room or via a ceiling plenum. Within the CRAC units, heat is removed from the air stream via a refrigerant-cooled evaporator or a water-cooled heat exchanger connected to typically a hydronic network, which rejects heat to the external environment via cooling towers.

In the environment as in Fig. 2, one typical issue is the “short circuit” of air flows from the

hot aisle to the cold aisle, due to the uneven distribution of the pressure around the racks. This is usually caused by the lack of enough cold air to meet the demand of the racks. Re-circulation of the exhaust air causes “hot spots” in the front of the racks. From operation point of view, the temperatures of these “hot spots” are proxies of the cooling demand at the spots. They can be used as the metrics to drive cooling facility control. To measure the inlet temperatures of the racks, a distributed network of sensors may be built (Bash et al. 2006). A MIMO controller would be ideal to manipulate the CRAC units and maintain the inlet temperatures at or below the thresholds while minimizing the cooling cost, e.g., the total blower power of the CRAC units. However, it is almost impossible to derive the models similar as in (1) because of the large scale of data center cooling facility. Given that one CRAC unit may provide cooling air for certain zone, and the boundary of the zones varies slowly when the system runs around equilibrium, the cooling systems may be decomposed into multiple zones, and each is cooled approximately by one CRAC unit and controlled by a SISO controller. In Bash et al. (2006), the effective zone of each CRAC unit was identified. A dominant temperature was then discovered from each zone to drive the controller. PID controllers, together with a set of rules to discover the dominant sensors, were shown effective for tuning the blower speeds and supplied air temperatures of the CRAC units.

The open environment as in Fig. 2 was popular due to its low cost to build. However, the

Facility Control and Optimization Problems in Data Centers, Fig. 2 Raised floor data center with isolated and open aisles

re-circulation and “hot spots” make the dynamic thermal control difficult. Cooling capacity can still be over-provisioned since the operation of the CRAC unit for each zone is dominated by one local “hot spot.” To address these issues, new architecture designs were introduced in the last decade. In order to prevent re-circulation of hot air, the hot or cold aisles are contained by walls or other barriers. In the ideal case, what the CRAC units need to do is then to provide enough volume of cold air, e.g., to maintain constant pressure drops between cold aisles and hot aisles. Containment of hot aisles has been popular in practice. Other architecture changes include moving the cooling units closer to the racks, e.g., in-row cooling (Barroso et al. 2018) where the fan coils are installed on the top of the hot aisles or at the end of racks together with hot aisle containment. This new architecture can support higher power density and help reduce the mechanical work to move the cold air flows. From dynamic control point of view, local SISO temperature and pressure control may be good enough.

Run-Time Optimization of Cooling Efficiency

The standard organization ASHRAE created the guideline for the inlet air for ICT equipment (ASHRAE 2016), where ranges of recommended or allowable temperature and humidity are specified. Following the guideline will guarantee thermal safety for the ICT equipment, but not necessarily result in the highest efficiency. There are a few tradeoffs at data center level for efficiency optimization as represented below.

- Intuitively, increasing the inlet air temperature setpoints is desirable since it will reduce the power by the cooling facility. However, as implied in (1), raising the inlet air temperature will result in higher server fan power, higher volume rate of air flows, and then more power consumed by the blowers of the CRAC units. It is also well-known that the leakage power of integrated circuits increases with temperature,

which is not negligible at the data center scale (Walsh et al. 2010).

- As implied in (1)–(3), cooling efficiency at data center level is also a spatial and temporal variant especially in the open environment. Moving workload around can potentially improve the overall energy efficiency.
- Nonlinearity exists with almost all of the facility equipment, such as the efficiency and capacity curves of the equipment like blowers, compressors, and pumps. When the capacity of multiple units is shared, minimizing the aggregate energy consumption while meeting the cooling demand is an opportunity.

However, online optimization at data center scale is difficult due to lack of models. First-principal models may be developed for offline analysis for small-scale data centers. One such set of thermal and fluid dynamic models were developed in Breen et al. (2010) for facility systems from chips to cooling towers. This “white-box” approach delivers insights but is hard to be applied to large-scale data centers. In data centers that are measured extensively, large datasets are available for machine-learning-based approaches to build “black-box” models. As discussed in Gao (2014), neural network models were developed from the big data sets collected in Google data centers throughout the years. The models can then be used to guide configuration of facilities, e.g., temperature setpoints, and run what-if analysis.

More Control and Optimization Issues

Facility equipment such as the hydronic network of chillers, cooling towers, water economizers, and air economizers usually have their own control kits from the manufactures. These units, however, can still be manipulated through the knobs exposed by the kits, e.g., chilled water setpoints or the interface to turn on or off the units. Understanding and modeling the units themselves, the interaction between the units, and the interaction between the facility and the ICT equipment are

always important for development of the data center level control and optimization systems.

Power control is another important topic for data center facility management. There are multiple knobs for manipulating power consumption, e.g., DVFS (Dynamic Voltage/Frequency Scaling) of processors, turning on/off servers. Workload migration, consolidation, or reduction may affect the power demand as well. Power may be regulated to follow the change of the workload or capped for thermal or electrical safety purposes. The reference Wang and Ranganathan (2014) provides comprehensive discussions on related problems, architecture, model development, and control/optimization algorithms.

Future Directions for Research

Online efficiency optimization is still challenging. Machine-learning-based approaches are promising, not only for data center operation but also for the operation of the individual facility units such as heat exchangers or chiller sets.

Reliability is a critical concern for which dynamic control can play an important role. As one example, upon the failure of one or more facility units, e.g., CRAC units, a controller needs to respond promptly to deliver enough cooling capacity. Designs are usually intuitive. Formal investigation is needed for the effectiveness and the stability. In another example, many facility units are managed by individual kits. Formal study is desirable on the interaction between the units and the global stability of the overall system.

Data center is a typical cyber-physical system (CPS) where the physical facility, the ICT equipment, the hosted applications and services, and the life of people in the world are tightly connected. Opportunities exist to explore the data center control and optimization problems from CPS point of view (Parolini et al. 2012).

Fault Detection and Diagnosis

Janos Gertler

George Mason University, Fairfax, VA, USA

Abstract

The fundamental concepts and methods of fault detection and diagnosis are reviewed. Faults are defined and classified as additive or multiplicative. The model-free approach of alarm systems is described and critiqued. Residual generation, using the mathematical model of the plant, is introduced. The propagation of additive and multiplicative faults to the residuals is discussed, followed by a review of the effect of disturbances, noise, and model errors. Enhanced residuals (structured and directional) are introduced. The main residual generation techniques are briefly described, including direct consistency relations, parity space, and diagnostic observers. Principal component analysis and its application to fault detection and diagnosis are outlined. The entry closes with some thoughts about future directions.

Keywords

Fault detection · Fault diagnosis · Residual generation · Consistency relations · Parity space · Diagnostic observers · Principal component analysis

Introduction

Faults are malfunctions of various elements of technical systems. Extreme cases of faults, called *failures*, are catastrophic breakdowns of the same. The technical systems (*the “plant”*) we are concerned with range from complex production systems (chemical plants, oil refineries, power stations) through major transportation equipment (airplanes, ships) to consumer machines (automobiles, home-heating systems, etc.). The faults may affect various parts of the main technical system (motors, pumps, storage tanks, pipelines) or devices interfacing the main technical system with computers providing for control, monitoring, and operator information. These latter include *sensors* (measuring devices) and *actuators* (devices acting on the process, such as valves).

The objective of *fault detection* is to determine and signal if there is a fault anywhere in the system. *Fault diagnosis* is aimed at providing more specific information about the fault; *fault isolation* is to pinpoint the component(s) (sensors, actuators, or plant components) where the fault is located, while *fault identification* is to determine (estimate) the size of the fault and, in some cases, the time of its arrival. With the ubiquitous presence of the computer, fault detection and diagnosis (FDD) is, in general, a function of the computer interfaced to the plant.

The simplest approaches to FDD consist of comparing individual plant measurements to preset limits, without utilizing any knowledge of the plant model (*limit checking* or “*alarm systems*”). More sophisticated techniques rely on an explicit mathematical model of the plant. They compare plant measurements to estimates obtained, from other measurements, by the model; any discrepancy may be an indication of faults. Another class of techniques (generally but incorrectly called “*data driven*”), most notably principal component analysis (PCA), include the estimation of an implicit model, from empirical plant data, and then use this in ways similar to the model-based methods. These approaches will be described in more detail in the sequel.

Alarm Systems

Alarm systems rely on the comparison of individual plant measurements to their respective limits. The limits may be two- or one-sided (upper and lower limit or upper limit only) and may have one or two levels (preliminary and full alarm). Momentary comparisons may be extended to include trend checks. Alarm systems are relatively simple but suffer from two major shortcomings:

- They have very limited fault specificity. A variable exceeding its limit is not a fault but a symptom of faults. A single component fault may cause alarm on many variables and a particular alarm may be due to various component faults.
- They have limited fault sensitivity. What is “normal” for a plant output variable depends on the value of the plant inputs. Such relationship, however, cannot be considered without a plant model; therefore, the alarm thresholds need to be set conservatively high.

Because of their simplicity, and despite the above shortcomings, alarm systems are widely used in industrial applications.

Model-Based FDD Concepts

Model-based methods utilize an explicit mathematical model of the plant. Such model is obtained usually from empirical plant data by systems identification methods or, exceptionally, from the “first principles” understanding of the plant. Model building, though critical to the success of model-based FDD, is usually not considered part of the FDD effort. The models may be linear or nonlinear, static or dynamic, and continuous- or discrete-time. In FDD, most frequently linear discrete-time dynamic models are used.

The fundamental idea of model-based FDD is the comparison of measured plant outputs to

Fault Detection and Diagnosis, Fig. 1 The concept of residual generation

their estimates, obtained, via the mathematical model, from measured or actuated plant inputs (Fig. 1).

Any discrepancy is (at least ideally) an indication that a fault (or faults) is (are) present in the system. Mathematically, the difference between the measured output $y_i(t)$ and its estimate $\hat{y}_i(t)$ is a (primary) residual (Willsky 1976):

$$e_i(t) = y_i(t) - \hat{y}_i(t)$$

In general, residuals are quantities that are zero in the absence of faults and nonzero in their presence.

Unfortunately, it is not only the faults that can make the residuals nonzero. Usually the plant is subject to disturbances (unmeasured deterministic inputs) and noise (unmeasured random inputs) (Fig. 1). In addition, and most importantly, model-based FDD is subject to model errors (either due to initial inaccuracies in model building or to changes in the physical plant) (Isermann 1984). The FDD algorithm should be designed, as much as possible, to be insensitive to noise and “robust” in face of disturbances and model errors.

Additive and multiplicative faults Depending on the way they appear in the system equations, faults may be additive or multiplicative. Additive faults are sensor and actuator biases,

leaks in the plant, etc. Multiplicative faults are changes in the plant parameters. In the following input-output relationship, $\mathbf{u}(t)$ is the vector of observed (measured or commanded) plant inputs, $\mathbf{y}(t)$ is the vector of measured plant outputs, and $\mathbf{p}(t)$ is the vector of additive faults; t is the discrete time. $\mathbf{M}(q)$ and $\mathbf{S}(q)$ are transfer function matrices in the shift operator q , and θ is the vector of plant parameters. Then,

$$\mathbf{y}(t) = \mathbf{M}(q, \theta)\mathbf{u}(t) + \mathbf{S}(q, \theta)\mathbf{p}(t)$$

The (“primary”) residual vector $\mathbf{e}(t)$, in response to additive faults, is

$$\mathbf{e}(t) = \mathbf{y}(t) - \mathbf{M}(q, \theta)\mathbf{u}(t) = \mathbf{S}(q, \theta)\mathbf{p}(t)$$

If there are multiplicative faults, then $\theta = \theta^\circ + \Delta\theta$, where θ° is the nominal parameter vector and $\Delta\theta$ is its change (the parametric fault); now the residual vector $\mathbf{e}(t)$ is (Gertler 1998)

$$\begin{aligned}\mathbf{e}(t) &= \mathbf{y}(t) - \mathbf{M}(q, \theta^\circ)\mathbf{u}(t) \\ &= \sum_j (\partial \mathbf{M}(q, \theta) / \partial \theta_j) \mathbf{u}(t) \Delta \theta_j\end{aligned}$$

Enhanced residuals To facilitate the isolation of faults, the primary residuals $\mathbf{e}(t)$ are subject to some enhancement manipulation. The three widely used enhancement techniques are:

- *Structured residuals*, whereas each residual is selectively sensitive to a subset of faults, resulting in a fault-specific set of zero/nonzero residuals upon a particular fault (fault codes);
- *Directional residuals*, whereas the residual vector maintains a fault-specific direction in response to each particular fault;
- *Diagonal residuals*, whereas each residual responds only to a particular fault.

Residual generators take the input and output observations from the plant and generate enhanced residuals by one of the above schemes, utilizing the mathematical model of the plant (Fig. 2).

Fault Detection and Diagnosis, Fig. 2 Residual generator

Dealing with noise Noise is practically unavoidable in physical systems. In FDD, basically two steps may be taken to reduce the effect of noise:

- *Residual filtering*. This can be achieved by basing decisions on moving averages of the residuals, or by applying explicit low-pass filters to the residuals, or by designing the residual generators in such a way that they have built-in low-pass behavior.
- *Statistical testing of the residuals*. Structured residuals are tested individually, as scalars, against thresholds; each residual is then represented by a Boolean 1 or 0, depending on the outcome of the test. Directional residuals are tested as vectors against multivariable distributions. The test thresholds are determined either theoretically, using assumptions for the source noise, or empirically based on measurements from fault-free operating conditions.

Dealing with disturbances Additive disturbances are unmeasurable inputs. If the disturbance-to-output transfer function (or

equivalent state-space representation) is known, then it is possible to design residuals that are completely decoupled from (insensitive to) those disturbances. However, the FDD algorithm is subject to a certain degree of “design freedom,” defined by the number of outputs in the physical system; disturbance decoupling is competing for this freedom with fault isolation enhancement. If there are too many disturbances, or if their path to the outputs is unknown, then only approximate decoupling is possible, making FDD also approximate, usually designed to optimize some (H-infinity) performance index.

Dealing with model errors Model errors are also unavoidable in most practical situations. This is the most serious obstacle in the application of model-based FDD techniques. In some very special cases, uncertainty of a particular plant parameter may be handled as a “multiplicative disturbance,” and residuals designed to be explicitly decoupled from it. In general, however, only approximate solutions are possible, reducing the residuals’ sensitivity to modeling errors, at the expense of also reducing their sensitivity to faults. Design methods utilizing some optimization techniques, mostly based on H-infinity or similar performance indices, are available in the literature (Edelmayer et al. 1994).

Residual Generation Methods For linear dynamic systems, provided exact (non-approximate) solution is possible, there are three major techniques to design residual generators: (i) direct consistency (parity) relations, (ii) parity space, and (iii) diagnostic observers. We will briefly introduce the three methods, for discrete-time plant models and additive faults. Note that though they look formally different, if designed for the same plant under the same design conditions, the three methods yield identical residuals (Gertler 1991).

Direct consistency (parity) relations (Gertler 1998). The input-output model of the plant is utilized directly in the design. The enhanced residuals are obtained from the primary residuals by a transformation $\mathbf{W}(q)$:

$$\begin{aligned}\mathbf{r}(t) &= \mathbf{W}(q)\mathbf{e}(t) = \mathbf{W}(q)[\mathbf{y}(t) - \mathbf{M}(q)\mathbf{u}(t)] \\ &= \mathbf{W}(q)\mathbf{S}(q)\mathbf{p}(t)\end{aligned}$$

The desired behavior of the residuals is specified as $\mathbf{r}(t) = \mathbf{Z}(q)\mathbf{p}(t)$, where the specification $\mathbf{Z}(q)$ contains the basic residual properties (structure or directions) plus the residual dynamics. The resulting design condition is $\mathbf{W}(q)\mathbf{S}(q) = \mathbf{Z}(q)$. If the $\mathbf{S}(q)$ matrix is square, which is usually the case (Gertler 1998), then this can be solved for $\mathbf{W}(q)$ by direct inversion. The residual generator has to be causal and stable; this can always be achieved by the appropriate modification of the dynamics in $\mathbf{Z}(q)$.

Parity space (Chow and Willsky 1984). This method, also known as the “Chow-Willsky scheme,” relies on the state-space description of the system:

$$\begin{aligned}\mathbf{x}(t+1) &= \mathbf{A}\mathbf{x}(t) + \mathbf{B}\mathbf{u}(t) + \mathbf{E}\mathbf{p}(t) \\ \mathbf{y}(t) &= \mathbf{C}\mathbf{x}(t) + \mathbf{D}\mathbf{u}(t) + \mathbf{F}\mathbf{p}(t)\end{aligned}$$

Stacking n consecutive output vectors $\mathbf{y}(t)$ (where n is the order of the model), and chain-substituting the state $\mathbf{x}(t)$, yields the equation

$$\mathbf{Y}(t) = \mathbf{J}\mathbf{x}(t-n) + \mathbf{K}\mathbf{U}(t) + \mathbf{L}\mathbf{P}(t)$$

where $\mathbf{Y}(t)$, $\mathbf{U}(t)$ and $\mathbf{P}(t)$ are stacked vectors and $\mathbf{J}$, $\mathbf{K}$ and $\mathbf{L}$ are hyper-matrices composed of the $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$, $\mathbf{D}$, $\mathbf{E}$, $\mathbf{F}$ matrices. Now

$$\mathbf{E}^*(t) = \mathbf{Y}(t) - \mathbf{K}\mathbf{U}(t) = \mathbf{L}\mathbf{P}(t) + \mathbf{J}\mathbf{x}(t-n)$$

would be a stacked vector of primary residuals, was it not for the presence of the inaccessible initial state $\mathbf{x}(t-n)$. To obtain true residuals, a transformation $r_i(t) = \mathbf{w}_i^T \mathbf{E}^*(t)$ is necessary, so that $\mathbf{w}_i^T \mathbf{J} = \mathbf{0}$. Any vector $\mathbf{w}_i$ satisfying this orthogonality condition is a *parity vector*, together spanning the *parity space*. Any parity vector yields a true residual $r_i(t)$; they can be so chosen that a set of residuals possesses structured behavior.

Diagnostic observers Various observer schemes have been extensively investigated as possible residual generator algorithms. The basic full-order *Luenberger observer* (assuming $\mathbf{D}=\mathbf{0}$) is

$$\hat{\mathbf{x}}(t+1) = \mathbf{A}\hat{\mathbf{x}}(t) + \mathbf{B}\mathbf{u}(t) + \mathbf{K}\mathbf{e}(t)$$

where $\mathbf{K}$ is the observer gain matrix and

$$\mathbf{e}(t) = \mathbf{y}(t) - \mathbf{C}\hat{\mathbf{x}}(t)$$

is the innovation vector. If the observer is stable then, apart from the start-up transient of the observer, the innovation qualifies as the primary residual. The gain matrix $\mathbf{K}$ is the major design parameter; it is chosen to place the observer poles, thus achieving stability and desired dynamic behavior (e.g., transient response and noise suppression). The remaining design freedom can be utilized to influence residual properties. The latter can be further affected by the transformation $\mathbf{r}(t) = \mathbf{H}\mathbf{e}(t)$, where the $\mathbf{H}$ matrix is an additional design parameter. Diagnostic observers can be designed for both structured and directional residuals (Chen and Patton 1999; White and Speyer 1987). Other observer schemes, most notably the *unknown input observer*, have also been proposed (Frank and Wunnenberg 1989). Because of their complexity, the detailed design procedures of diagnostic observers go beyond the scope of this entry.

Principal Component Analysis

Principal component analysis is extensively used in the monitoring of complex plants with hundreds of variables because, by revealing linear relations among the variables, it significantly reduces the dimensionality of the plant model (Kresta et al. 1991). When PCA is applied for FDD, it implies two phases. In the training phase, an implicit plant model is created from empirical plant data. In the monitoring phase, this model is used for FDD.

Training data (measured inputs and outputs) are collected from the plant during fault-free operation. The covariance matrix of the data is formed and its eigenstructure obtained. Due to

linear relations among the data, some of the eigenvalues will be zero (or near-zero, in the presence of noise). The eigenvectors belonging to the nonzero eigenvalues form the *data space*, where the fault-free data exist, while those belonging to the zero eigenvalues form the *residual space*.

It is the residual space that is utilized for FDD. The projection of a measurement vector onto the residual space is the (primary) residual. A statistical test on its size leads to a detection decision (absence or presence of faults). A threshold test is necessary because noise also causes nonzero residuals. An analysis of the eigenvectors spanning the residual space shows how the various faults propagate to the primary residual. This allows for the design of residual manipulations yielding structured or directional residuals, just like in the FDD methods based on exact models (Gertler et al. 1999).

The procedure as described above applies to sensor and actuator faults; inclusion of plant faults requires extra effort (and experiments). Also, PCA is primarily meant for static models. Its extension to discrete-time dynamic models is straightforward, but it increases the size of the model, proportionally to the dynamic order of the model.

Summary and Future Directions

The theoretical and methodological foundations of fault detection and diagnosis were laid in the 1980s and early 1990s. Today FDD is a mature field within systems and control engineering. There is a very significant level of activity, as measured in published papers and conference contributions.

There are still open problems in various areas, such as extensions to nonlinear or parameter varying systems (Senname et al. 2013). Also, the proliferation of networked, distributed, and cooperative systems is raising a whole range of exciting challenges for FDD, calling for decentralized, distributed, or cooperative diagnosis techniques (Blanke et al. 2016; Fang et al. 2007).

Several “classical” application areas of FDD have gained new significance with the dramatic development of the target system: on-board

automotive FDD with the arrival of self-driving cars or aerospace FDD with the proliferation of unmanned aerial vehicles (Isermann 2010). Electric cars bring into new focus the diagnosis of classical electrical systems. The spread of wind turbines and turbine farms has opened a whole new field for FDD applications, both at the individual device level and as a network problem (Simani and Castaldi 2019). With tighter water resources management, FDD in water distribution networks is gaining significance (Puig et al. 2017). These application problems are visible in conference programs and technical journals. What is more important, with the ever-growing availability of computing power and a welcome evolution of industrial attitude, FDD technology now increasingly finds its way to a broad spectrum of real-life applications.

Fault Detection and Diagnosis: Computational Issues and Tools

Andreas Varga
Gilching, Germany

Abstract

Two basic fault diagnosis problems are formulated for linear time-invariant systems with additive faults, and general existence conditions of their solutions are given. Several computational paradigms are discussed, which are instrumental for the development of efficient and numerically reliable synthesis procedures for the design of fault detection filters. An overview of the available computational software tools is presented.

Keywords

CACSD · Fault detection and diagnosis · Fault detection and isolation · Numerical methods · Software tools

Introduction

The theoretical developments for the model-based fault detection and diagnosis for linear time-invariant systems are essentially completed. Also, the development of numerically reliable computational procedures for the synthesis of fault detection filters has been mostly finalized in the last decade. The new generation of synthesis procedures is well suited as the basis of implementation of versatile software tools, which allow the solution of synthesis problems in the most general setting using the best available numerical methods. This entry presents an overview of these recent developments both in the computational synthesis procedures and associated software tools. Therefore, this presentation complements two other entries of this encyclopedia: ► [Fault Detection and Diagnosis](#) and ► [Robust Fault Diagnosis and Control](#).

Two basic synthesis problems of fault detection filters are formulated and general solvability conditions are given, which guarantee the existence of the solutions in the most general setting, for both continuous- and discrete-time systems. For each of the formulated problems, general synthesis procedures are presented. The development of these procedures relies on several computational paradigms, which are discussed in details.

Plant Models with Additive Faults

The plant models underlying the discussed synthesis methods (also called *synthesis models*) are linear time-invariant (LTI) system models, where the faults are equated with special (unknown) disturbance inputs. An important class of models with additive faults arises when defining the fault signals for two main categories of faults, namely, actuator and sensor faults. Two basic forms of synthesis models are used.

The input-output plant model with additive faults has the form

$$\mathbf{y}(\lambda) = G_u(\lambda)\mathbf{u}(\lambda) + G_d(\lambda)\mathbf{d}(\lambda) + G_f(\lambda)\mathbf{f}(\lambda) + G_w(\lambda)\mathbf{w}(\lambda), \quad (1)$$

where $\mathbf{y}(\lambda)$, $\mathbf{u}(\lambda)$, $\mathbf{d}(\lambda)$, $\mathbf{f}(\lambda)$, and $\mathbf{w}(\lambda)$, with boldface notation, are the Laplace-transformed

(in the continuous-time case) or Z-transformed (in the discrete-time case) p -dimensional system output vector $y(t)$; m_u -dimensional control input vector $u(t)$; m_d -dimensional disturbance vector $d(t)$; m_f -dimensional fault vector $f(t)$; and m_w -dimensional noise vector $w(t)$, respectively, and where $G_u(\lambda)$, $G_d(\lambda)$, $G_f(\lambda)$, and $G_w(\lambda)$ are proper *transfer function matrices* (TFMs) from the respective inputs to outputs. Input-output models with additive faults of the form (1) are useful in formulating various fault diagnosis problems, in deriving general solvability conditions and in describing conceptual synthesis procedures. However, these models are generally not suited for numerical computations, due to the potentially high sensitivity of polynomial-based model representations.

For computational purposes, instead of the input-output model (1) with the compound TFM $[G_u(\lambda) \ G_d(\lambda) \ G_f(\lambda) \ G_w(\lambda)]$, an equivalent state-space model is used having the form

$$\begin{aligned} E\lambda x(t) &= Ax(t) + B_u u(t) + B_d d(t) \\ &\quad + B_f f(t) + B_w w(t), \\ y(t) &= Cx(t) + D_u u(t) + D_d d(t) \\ &\quad + D_f f(t) + D_w w(t), \end{aligned} \quad (2)$$

with the n -dimensional state vector $x(t)$, where $\lambda x(t) := \dot{x}(t)$ or $\lambda x(t) := x(t+1)$ depending on the type of the system, continuous- or discrete-time, respectively. The matrix E is generally invertible and is frequently taken as $E = I_n$. Plant models of the form (2) often arise from the linearization of nonlinear dynamic plant models in specific operation points and for fixed values of plant parameters. The noise inputs generally account for the effects of uncertainties (e.g., inherent variabilities in operating points and parameters).

Notation: To indicate the input-output equivalence of the models in (1) and (2), we use the notation

$$\begin{aligned} &[G_u(\lambda) \ G_d(\lambda) \ G_f(\lambda) \ G_w(\lambda)] \\ &= \left[\begin{array}{c|c} A - \lambda E & B_u \ B_d \ B_f \ B_w \\ \hline C & D_u \ D_d \ D_f \ D_w \end{array} \right]. \end{aligned}$$

Residual Generation

A nonzero fault signal $f \neq 0$ in (1) signifies a deviation from the normal behavior of the plant due to an unexpected event (e.g., physical component failure or supply breakdown). Generally, the occurrence of a fault must be detected as early as possible to prevent further degradation of the plant behavior. *Fault detection and diagnosis* (FDD) is concerned with one or more of the following aspects: the detection of the occurrence of any fault (*fault detection*), the localization of detected faults (*fault isolation*), the reconstruction of the fault signal (*fault estimation*), and the classification of the detected faults and determination of their characteristics (*fault identification*). In this entry we constrain the FDD problem only to the *fault detection* and *fault detection and isolation* (FDI) aspects.

A FDD system is a device (usually based on a collection of real-time processing algorithms) suitably set up to fulfill the above tasks. The minimal functionality of any FDD system is illustrated in Fig. 1.

The main component of any FDD system is the *residual generator* (or *fault detection filter*), which produces residual signals grouped in a q -dimensional vector r by processing the available measurements y and the known values of control inputs u . The role of the residual signals is to indicate the presence or absence of faults, and therefore the residual r must be equal (or close) to zero in the absence of faults and significantly different from zero after a fault occurs.

For decision-making when solving fault detection problems, a suitable measure of the residual magnitude is generated in a scalar evaluation signal θ (e.g., $\theta = \|r\|$), which is then used to set the corresponding decision variable ι as follows: $\iota = 1$, if $\theta > \tau$ for a detected fault, and $\iota = 0$ if $\theta \leq \tau$, for the lack of faults, where τ is a given detection threshold.

For decision-making when solving FDI problems, $r(t)$ is generally a structured vector with, say n_b components $r^{(i)}(t)$, $i = 1, \dots, n_b$, and θ and ι are n_b -dimensional vectors, with θ_i representing a measure of the magnitude of the i -th residual component (e.g., $\theta_i = -\|r^{(i)}\|$). The i -th component of the binary signature vector ι is set $\iota_i = 1$ or $\iota_i = 0$ corresponding to a fired (i.e., $\theta_i > \tau$) or not fired (i.e., $\theta_i \leq \tau$) component $r^{(i)}(t)$, respectively.

A linear residual generator employed in the FDD system in Fig. 1 has the input-output form

$$\mathbf{r}(\lambda) = Q(\lambda) \begin{bmatrix} \mathbf{y}(\lambda) \\ \mathbf{u}(\lambda) \end{bmatrix}, \quad (3)$$

where $Q(\lambda)$ is the TFM of the filter. For a physically realizable filter, $Q(\lambda)$ must be *stable* (i.e., with all its poles having negative real parts for a continuous-time system or magnitudes less than one for a discrete-time system). The *order* of $Q(\lambda)$ is the dimension of the state vector of a minimal state-space realization of $Q(\lambda)$. The dimension q of the residual vector $r(t)$ depends on the fault diagnosis problem to be solved. The input-output representation (3) is called the

Fault Detection and Diagnosis: Computational Issues and Tools, Fig. 1 Basic fault diagnosis setup

implementation form of the fault detection filter and is the basis of its real-time implementation.

The residual signal $r(t)$ in (3) generally depends via the system outputs $y(t)$ of all system inputs $u(t)$, $d(t)$, $f(t)$, and $w(t)$. The *internal form* of the filter is obtained by replacing in (3) $y(\lambda)$ by its expression in (1), and is given by

$$\begin{aligned} \mathbf{r}(\lambda) = & R_u(\lambda)\mathbf{u}(\lambda) + R_d(\lambda)\mathbf{d}(\lambda) \\ & + R_f(\lambda)\mathbf{f}(\lambda) + R_w(\lambda)\mathbf{w}(\lambda), \end{aligned} \quad (4)$$

where

$$\begin{aligned} & [R_u(\lambda) \mid R_d(\lambda) \mid R_f(\lambda) \mid R_w(\lambda)] \\ & := Q(\lambda) \begin{bmatrix} G_u(\lambda) & G_d(\lambda) & G_f(\lambda) & G_w(\lambda) \\ I_{m_u} & 0 & 0 & 0 \end{bmatrix}. \end{aligned} \quad (5)$$

For a successfully designed filter $Q(\lambda)$, all TFMs in the corresponding internal form (4) are stable and fulfill specific fault diagnosis requirements.

The basic functionality of a well-designed fault detection filter is to ensure the lack of false alarms, in the case when no faults occurred, and the lack of missed detection of faults, in the case of occurrence of a fault. The first requirement is fulfilled if, in the presence of noise, the signal norm $\|r\|$ is sufficiently small for all possible control, disturbance, and noise inputs. The requirement on the lack of missed detections is fulfilled provided $\|r\|$ is sufficiently large for any fault of sufficiently large magnitude for all possible control, disturbance, and noise inputs.

Fault Diagnosis Problems

Two basic fault diagnosis problems are formulated in what follows. To fulfill the requirement for the lack of false alarms, for both problems we require that by a suitable choice of a stable fault detection filter $Q(\lambda)$, we achieve that the residual signal $r(t)$ is fully decoupled from the control input $u(t)$ and disturbance input $d(t)$. Thus, the following *decoupling conditions* must be generally fulfilled:

$$\begin{aligned} (i) \quad & R_u(\lambda) = 0, \\ (ii) \quad & R_d(\lambda) = 0. \end{aligned} \quad (6)$$

Since the effect of a nonzero noise input $w(t)$ can usually not be fully decoupled from the residual $r(t)$, an additional requirement is that the influence of the noise signal $w(t)$ is negligible. Thus, the following *noise attenuation condition* has to be fulfilled:

$$(iv) \quad R_w(\lambda) \approx 0, \text{ with } R_w(\lambda) \text{ stable.} \quad (7)$$

The condition $R_w(\lambda) \approx 0$ expresses the requirement that the transfer gain $\|R_w(\lambda)\|$ (measured by any suitable norm) can be made arbitrarily small.

For particular fault diagnosis problems specific requirements on $R_f(\lambda)$ have to be additionally fulfilled. In what follows, we formulate two basic fault diagnosis problems, for which we also give necessary and sufficient conditions for the existence of their solutions (for proofs see Varga 2017).

Fault Detection Problem: FDP

The basic additional requirement is simply to achieve, by a suitable choice of a fault detection filter $Q(\lambda)$, that in the absence of noise input (i.e., $w(t) = 0$), the residual $r(t)$ is influenced by all fault components $f_j(t)$, $j = 1, \dots, m_f$. Let $R_{f_j}(\lambda)$ denote the j -th column of $R_f(\lambda)$. This requirement can be expressed as the following *detection condition* to be fulfilled for all faults:

$$\begin{aligned} (iv) \quad & R_{f_j}(\lambda) \neq 0, \\ & j = 1, \dots, m_f \text{ with } R_f(\lambda) \text{ stable.} \end{aligned} \quad (8)$$

The solvability conditions of the FDP are simple rank conditions involving only the TFMs from the disturbances and faults:

Theorem 1 *For the system (1), the FDP is solvable if and only if*

$$\begin{aligned} & \text{rank}[G_d(\lambda) \ G_{f_j}(\lambda)] > \text{rank } G_d(\lambda), \\ & j = 1, \dots, m_f, \end{aligned} \quad (9)$$

where $G_{f_j}(\lambda)$ denotes the j -th column of $G_f(\lambda)$. Here, $\text{rank } G(\lambda)$ denotes the normal rank of the rational TFM $G(\lambda)$, representing the maximal rank of the complex matrix $G(\lambda)$ over all values of $\lambda \in \mathbb{C}$ such that $G(\lambda)$ has finite norm.

For fault diagnosis applications, the importance of solving FDPs primarily lies in the fact that the solution of the (more involved) fault isolation problems can be addressed by successively solving several appropriately formulated FDPs.

Fault Detection and Isolation Problem: FDIP

For the isolation of faults, we employ residual generator filters formed by stacking a bank of n_b filters of the form

$$\mathbf{r}^{(i)}(\lambda) = Q^{(i)}(\lambda) \begin{bmatrix} \mathbf{y}(\lambda) \\ \mathbf{u}(\lambda) \end{bmatrix}, \quad (10)$$

where the i -th filter $Q^{(i)}(\lambda)$ generates the corresponding i -th residual component $r^{(i)}(t)$ (scalar or vector). This leads to the following structured residual vector $r(t)$ and block-structured filter $Q(\lambda)$

$$r(t) = \begin{bmatrix} r^{(1)}(t) \\ \vdots \\ r^{(n_b)}(t) \end{bmatrix}, \quad Q(\lambda) = \begin{bmatrix} Q^{(1)}(\lambda) \\ \vdots \\ Q^{(n_b)}(\lambda) \end{bmatrix}. \quad (11)$$

The resulting $R_f(\lambda)$ is an $n_b \times m_f$ block-structured TFM of the form

$$R_f(\lambda) = \begin{bmatrix} R_{f_1}^{(1)}(\lambda) & \cdots & R_{f_{m_f}}^{(1)}(\lambda) \\ \vdots & \ddots & \vdots \\ R_{f_1}^{(n_b)}(\lambda) & \cdots & R_{f_{m_f}}^{(n_b)}(\lambda) \end{bmatrix}, \quad (12)$$

where the (i, j) -th block of $R_f(\lambda)$ is defined as

$$R_{f_j}^{(i)}(\lambda) := Q^{(i)}(\lambda) \begin{bmatrix} G_{f_j}(\lambda) \\ 0 \end{bmatrix}$$

and describes how the j -th fault f_j influences the i -th residual component $r^{(i)}(t)$.

We associate to the block-structured $R_f(\lambda)$ in (12) the $n_b \times m_f$ binary structure matrix S_{R_f} ,

whose (i, j) -th element is defined as

$$\begin{aligned} S_{R_f}(i, j) &= 1 \quad \text{if } R_{f_j}^{(i)}(\lambda) \neq 0, \\ S_{R_f}(i, j) &= 0 \quad \text{if } R_{f_j}^{(i)}(\lambda) = 0. \end{aligned} \quad (13)$$

If $S_{R_f}(i, j) = 1$ then we say that the residual component $r^{(i)}$ is sensitive to the j -th fault f_j , while if $S_{R_f}(i, j) = 0$ then the j -th fault f_j is decoupled from $r^{(i)}$. The m_f columns of S_{R_f} are called *fault signatures*. Since each nonzero column of S_{R_f} is associated with the corresponding fault input, fault isolation can be performed by comparing the resulting binary decision vector ι in Fig. 1 (i.e., the signatures of fired or not fired residual components) with the fault signatures coded in the columns of S_{R_f} .

For a given $n_b \times m_f$ structure matrix S , the FDIP requires the determination of a stable filter $Q(\lambda)$ of the form (11) such that for the corresponding block-structured $R_f(\lambda)$ in (12), the following condition is additionally fulfilled:

$$(iv) \quad S_{R_f} = S, \quad \text{with } R_f(\lambda) \text{ stable.} \quad (14)$$

The solution of the FDIP can be addressed by solving n_b suitably formulated FDPs. The i -th FDP arises by reformulating the i -th FDIP for determining the i -th filter $Q^{(i)}(\lambda)$ in (10) for a structure matrix which is the i -th row of S . This can be accomplished by redefining the fault components corresponding to zero entries in the i -th row of S as additional disturbance inputs to be decoupled in the i -th residual component $r^{(i)}(t)$. Let $\widehat{G}_d^{(i)}(\lambda)$ be the corresponding TFM formed from the columns of $G_f(\lambda)$ for which $S_{ij} = 0$. We have the following solvability conditions for the FDIP, which simply express the solvability of the n_b FDPs formulated for the n_b rows of S :

Theorem 2 For the system (1) and a given $n_b \times m_f$ structure matrix S , the FDIP is solvable if and only if for $i = 1, \dots, n_b$

$$\begin{aligned} &\text{rank} [G_d(\lambda) \quad \widehat{G}_d^{(i)}(\lambda) \quad G_{f_j}(\lambda)] \\ &> \text{rank} [G_d(\lambda) \quad \widehat{G}_d^{(i)}(\lambda)] \end{aligned} \quad (15)$$

for all j such that $S_{ij} \neq 0$.

Synthesis of Fault Detection Filters

Several computational paradigms are instrumental in developing generally applicable, numerically reliable, and computationally efficient synthesis methods of residual generators. In what follows we shortly review these paradigms and discuss their roles in the synthesis procedures.

Nullspace-Based Synthesis

An important synthesis paradigm is the use of the nullspace method as a first synthesis step to ensure the fulfillment of the decoupling conditions $R_u(\lambda) = 0$ and $R_d(\lambda) = 0$ in (6). This can be done by choosing $Q(\lambda)$ of the form

$$Q(\lambda) = \overline{Q}_1(\lambda) Q_1(\lambda), \quad (16)$$

where the factor $Q_1(\lambda)$ is a left nullspace basis of the rational matrix

$$G(\lambda) := \begin{bmatrix} G_u(\lambda) & G_d(\lambda) \\ I_{m_u} & 0 \end{bmatrix}. \quad (17)$$

For any $Q(\lambda)$ of the form (16), we have

$$[R_u(\lambda) \ R_d(\lambda)] = Q(\lambda)G(\lambda) = 0.$$

With (16), the fault detection filter in (3) can be rewritten in the alternative form

$$\mathbf{r}(\lambda) = \overline{Q}_1(\lambda) Q_1(\lambda) \begin{bmatrix} \mathbf{y}(\lambda) \\ \mathbf{u}(\lambda) \end{bmatrix} = \overline{Q}_1(\lambda) \overline{\mathbf{y}}(\lambda), \quad (18)$$

where

$$\begin{aligned} \overline{\mathbf{y}}(\lambda) &:= Q_1(\lambda) \begin{bmatrix} \mathbf{y}(\lambda) \\ \mathbf{u}(\lambda) \end{bmatrix} \\ &= \overline{G}_f(\lambda) \mathbf{f}(\lambda) + \overline{G}_w(\lambda) \mathbf{w}(\lambda), \end{aligned} \quad (19)$$

with

$$[\overline{G}_f(\lambda) \ \overline{G}_w(\lambda)] := Q_1(\lambda) \begin{bmatrix} G_f(\lambda) & G_w(\lambda) \\ 0 & 0 \end{bmatrix}. \quad (20)$$

With this first preprocessing step, we reduced the original problems formulated for the system (1) to simpler ones, which can be formulated for the

reduced system (19) (without control and disturbance inputs), for which we have to determine the TFM $\overline{Q}_1(\lambda)$ of the simpler fault detection filter (18).

At this stage we can assume that both $Q_1(\lambda)$ and the TFMs of the reduced system (19) are proper and even stable. This can be always achieved by replacing $Q_1(\lambda)$, with a stable basis $M(\lambda)Q_1(\lambda)$, where $M(\lambda)$ is an invertible, stable TFM, such that $M(\lambda)[Q_1(\lambda) \ \overline{G}_f(\lambda) \ \overline{G}_w(\lambda)]$ is stable. Such an $M(\lambda)$ can be determined as the (minimum-degree) denominator of a stable left coprime factorization of $[Q_1(\lambda) \ \overline{G}_f(\lambda) \ \overline{G}_w(\lambda)]$.

Both synthesis problems can be equivalently reformulated to determine a filter $\overline{Q}_1(\lambda)$ for the reduced system (19), for which simpler solvability conditions hold. For the solvability of the FDP, we have the following corollary to Theorem 1.

Corollary 1 *For the system (1), the FDP is solvable if and only if*

$$\overline{G}_{f_j}(\lambda) \neq 0, \quad j = 1, \dots, m_f. \quad (21)$$

Similar simpler conditions hold for the solvability of the FDIP.

Filter Updating Techniques

In many synthesis procedures, the TFM of the resulting filter $Q(\lambda)$ can be expressed in a factored form as

$$Q(\lambda) = Q_K(\lambda) \cdots Q_2(\lambda) Q_1(\lambda), \quad (22)$$

where $Q_1(\lambda)$ is a left nullspace basis of $G(\lambda)$ in (17) satisfying $Q_1(\lambda)G(\lambda) = 0$, and $Q_1(\lambda)$, $Q_2(\lambda)Q_1(\lambda)$, ..., can be interpreted as partial syntheses addressing specific requirements. Since each partial synthesis may represent a valid fault detection filter, this approach can be flexibly used for employing or combining different synthesis techniques.

The determination of $Q(\lambda)$ in the factored form (22) can be formulated as a K -step synthesis procedure based on successive updating of an initial filter $Q = Q_1(\lambda)$ and the nonzero terms of its corresponding internal form

$$\begin{aligned} R(\lambda) &:= [R_f(\lambda) \ R_w(\lambda)] \\ &= Q_1(\lambda) \begin{bmatrix} G_f(\lambda) & G_w(\lambda) \\ 0 & 0 \end{bmatrix} \end{aligned}$$

as follows: for $k = 2, \dots, K$, do

Step k: Determine $Q_k(\lambda)$ using the current $Q(\lambda)$ and $R(\lambda)$ and then perform the updating as

$$Q(\lambda) \leftarrow Q_k(\lambda)Q(\lambda), \quad R(\lambda) \leftarrow Q_k(\lambda)R(\lambda).$$

The updating operations are efficiently performed using state-space description-based formulas. The state-space realizations of the TFMs $Q(\lambda)$ and $R(\lambda)$ in the implementation and internal forms can be jointly expressed in the generalized state-space (or descriptor system) representation

$$[Q(\lambda) \ R(\lambda)] = \left[\begin{array}{c|cc} A_Q - \lambda E_Q & B_Q & B_R \\ \hline C_Q & D_Q & D_R \end{array} \right]. \quad (23)$$

The state-space realizations of $Q(\lambda)$ and $R(\lambda)$ share the matrices A_Q , E_Q , and C_Q . The preservation of these forms at each updating step is the basis of the filter updating-based synthesis paradigm. To allow operations with non-proper TFMs (i.e., with singular E_Q), the use of the descriptor system representation is instrumental for developing numerically reliable computational algorithms.

The main benefit of using explicit state-space based updating formulas is the possibility to ensure at each step the cancellation of a maximum number of poles and zeros between the factors. This allows to keep the final order of the filter $Q(\lambda)$ as low as possible. In this way, the updating-based synthesis approach naturally leads to so-called *integrated computational algorithms*, with strongly coupled successive computational steps. Since the form of the realizations of $Q(\lambda)$ and $R(\lambda)$ in (23) are preserved, the stability is simultaneously achieved for both $Q(\lambda)$ and $R(\lambda)$ at the final synthesis step. At the last step, the standard state-space realization of $Q(\lambda)$ is usually recovered, to facilitate its real-time implementation.

Least Order Synthesis

The least order synthesis of fault detection filters means to determine filters $Q(\lambda)$ with the least possible orders, to help in reducing the computational burden associated with their real-time implementations. The main tool to achieve least order synthesis is the solution of suitable *minimal cover problems*. If $X_1(\lambda)$ and $X_2(\lambda)$ are rational matrices of the same column dimension, then the *left minimal cover problem* is to find $X(\lambda)$ and $Y(\lambda)$ such that

$$X(\lambda) = X_1(\lambda) + Y(\lambda)X_2(\lambda), \quad (24)$$

and the order of $[X(\lambda) \ Y(\lambda)]$ is minimal.

A typical second step in many synthesis procedures is to choose $Q_2(\lambda)$ such that the product $Q_2(\lambda)Q(\lambda)$ has least dynamical order and, simultaneously, a certain *admissibility* condition is fulfilled (usually involving the nonzero TFMs $R_f(\lambda)$ and $R_w(\lambda)$). For the solution of the FDP, the rows of $Q(\lambda) := Q_1(\lambda)$ form a left nullspace basis and the employed admissibility conditions are

$$Q_2(\lambda)R_{f_j}(\lambda) \neq 0, \quad j = 1, \dots, m_f, \quad (25)$$

which guarantee the detectability of all fault components, and additionally to (25), the full row rank requirement on $Q_2(\lambda)R_w(\lambda)$. The latter condition is only imposed for convenience, to simplify the subsequent computational steps.

The determination of candidate solutions $Q_2(\lambda)$ such that $Q_2(\lambda)Q(\lambda)$ has least order can be done by solving left minimal cover problems of the form (24), where $X_1(\lambda)$ and $X_2(\lambda)$ represent disjoint subsets of basis vectors, such that: $Q(\lambda) = \begin{bmatrix} X_1(\lambda) \\ X_2(\lambda) \end{bmatrix}$, $Q_2(\lambda) = [I \ Y(\lambda)]$, and $X(\lambda) = Q_2(\lambda)Q(\lambda)$ together with $Y(\lambda)$ represent the solution of the left cover problem. A systematic search over increasing orders of candidate solutions can be performed, and the search stops when the admissibility conditions are fulfilled.

Coprime Factorization Techniques

A desired dynamics of the resulting final filters $Q(\lambda)$ and $R(\lambda)$ can be enforced by choosing

a suitable invertible factor $M(\lambda)$, such that $M(\lambda)[Q(\lambda) \ R(\lambda)]$ has desired poles. This can be achieved by computing a left coprime factorization

$$[Q(\lambda) \ R(\lambda)] = M^{-1}(\lambda)[N_Q(\lambda) \ N_R(\lambda)]$$

with $M(\lambda)$ and $[N_Q(\lambda) \ N_R(\lambda)]$ coprime and having arbitrary stable poles, and then performing the updating operation

$$[Q(\lambda) \ R(\lambda)] \leftarrow [N_Q(\lambda) \ N_R(\lambda)].$$

To illustrate the state-space formulas based updating technique, we employ a realization of the denominator factor $M(\lambda)$ of the form

$$M(\lambda) = \left[\begin{array}{c|c} \frac{A_Q + KC_Q - \lambda E_Q}{C_Q} & \frac{K}{I} \end{array} \right],$$

where K (the so-called output injection gain matrix) is determined by eigenvalue assignment techniques to ensure stability (i.e., to assign the poles of $M(\lambda)$ to lie in a suitable stable region). Then, the numerator factors are obtained in forms compatible with $Q(\lambda)$ and $R(\lambda)$ in (23) as

$$N_Q(\lambda) = \left[\begin{array}{c|c} \frac{A_Q + KC_Q - \lambda E_Q}{C_Q} & \frac{B_Q + KD_Q}{D_Q} \end{array} \right],$$

$$N_R(\lambda) = \left[\begin{array}{c|c} \frac{A_Q + KC_Q - \lambda E_Q}{C_Q} & \frac{B_R + KD_R}{D_R} \end{array} \right].$$

Outer-Co-inner Factorization

The outer-co-inner factorization plays an important role in the solution of the FDP and FDIP. We only consider the particular case of a stable and full row rank rational matrix $G(\lambda)$, without zeros on the boundary of the stability region, which can be factored as

$$G(\lambda) = G_o(\lambda)G_i(\lambda), \quad (26)$$

where $G_o(\lambda)$ is the (invertible) minimum-phase outer factor (i.e., stable and having only stable zeros), and $G_i(\lambda)$ is co-inner (i.e., stable and $G_i(\lambda)G_i^{\sim}(\lambda) = I$; recall that $G_i^{\sim}(s) = G_i^T(-s)$

for a continuous-time system and $G_i^{\sim}(z) = G_i^T(1/z)$ for a discrete-time system).

In solving the formulated synthesis problems, $G(\lambda) = R_w(\lambda)$ and the optimal choice of the corresponding factor, say $Q_4(\lambda)$, is $Q_4(\lambda) = G_o^{-1}(\lambda)$, which is stable, because $G_o(\lambda)$ is minimum-phase.

Remark: In the case when $G(\lambda)$ has zeros on the boundary of the stability domain, a factorization as in (26) can still be computed, with $G_o(\lambda)$ containing, besides the stable zeros, also all zeros of $G(\lambda)$ on the boundary of the stability domain. In this case, the inverse $G_o^{-1}(\lambda)$ is unstable and/or improper. Such a case is called *non-standard* and, when it is encountered, requires a special treatment. We should emphasize that non-standard cases occur only in conjunction with employing a particular solution method and are generally not related to the solvability of the fault diagnosis problems.

Synthesis Procedures

To illustrate the application of the computational paradigms discussed in the previous section, we present in this section the detailed synthesis procedure to solve the FDP.

Procedure AFD

Inputs: $\{G_u(\lambda), G_d(\lambda), G_f(\lambda), G_w(\lambda)\}$

Outputs: $Q(\lambda), R_f(\lambda), R_w(\lambda)$

1. Compute a proper minimal left nullspace basis $Q_1(\lambda)$ of $G(\lambda)$ in (17); set $Q(\lambda) = Q_1(\lambda)$ and compute

$$R(\lambda) := [R_f(\lambda) \ R_w(\lambda)]$$

$$= Q_1(\lambda) \begin{bmatrix} G_f(\lambda) & G_w(\lambda) \\ 0 & 0 \end{bmatrix}.$$

2. **Exit** if $\exists j$ such that $R_{f_j}(\lambda) = 0$ (no solution). Choose a proper $Q_2(\lambda)$ such that $Q_2(\lambda)Q(\lambda)$ has least order, satisfies $Q_2(\lambda)R_{f_j}(\lambda) \neq 0 \ \forall j$, and $Q_2(\lambda)R_w(\lambda)$ has full row rank (admissibility); update $[Q(\lambda) \ R(\lambda)] \leftarrow Q_2(\lambda)[Q(\lambda) \ R(\lambda)]$.

3. Compute the left coprime factorization

$$[Q(\lambda) \ R(\lambda)] = Q_3^{-1}(\lambda) [N_Q(\lambda) \ N_R(\lambda)]$$

such that $N_Q(\lambda)$ and $N_R(\lambda)$ have desired stable dynamics; update $[Q(\lambda) \ R(\lambda)] \leftarrow [N_Q(\lambda) \ N_R(\lambda)]$.

4. Compute the outer-co-inner factorization $R_w(\lambda) = R_{wo}(\lambda)R_{wi}(\lambda)$, where the outer factor $R_{wo}(\lambda)$ is invertible; with $Q_4(\lambda) = R_{wo}^{-1}(\lambda)$ update $[Q(\lambda) \ R(\lambda)] \leftarrow Q_4(\lambda)[Q(\lambda) \ R(\lambda)]$.

This procedure also illustrates the flexibility of the factorization-based synthesis, which allows to skip some of the synthesis steps. For example, if the least order synthesis is not of interest, then $Q_2(\lambda) = I$ at Step 2, and if additionally, the resulting $Q_1(\lambda)$ at Step 1 has an already satisfactory dynamics, then $Q_3(\lambda) = I$ at Step 3. Step 4 need not be performed if no noise inputs are present. The occurrence of the non-standard case with $Q_4(\lambda) = R_{wo}^{-1}(\lambda)$ unstable at Step 4 can be simply handled, for example, by repeating the computations at Step 3 after performing Step 4.

The **Procedure AFD** serves as a computational kernel for solving the FDIP by computing repeatedly the solutions of appropriately formulated FDPs. The synthesis procedure described below applies at the first step the nullspace-based paradigm to enforce the decoupling conditions $R_u(\lambda) = 0$, $R_d(\lambda) = 0$, and to obtain the reduced system (19). Then, it solves, for each row of S , a FDP for a reduced system with redefined sets of disturbance and fault inputs. The synthesis procedure, additionally determines the block rows of $R_f(\lambda)$ and $R_w(\lambda)$ corresponding to $Q^{(i)}(\lambda)$ as

$$[R_f^{(i)}(\lambda) \ R_w^{(i)}(\lambda)] := Q^{(i)}(\lambda) \begin{bmatrix} G_f(\lambda) & G_w(\lambda) \\ 0 & 0 \end{bmatrix}.$$

Procedure AFDI

Inputs: $\{G_u(\lambda), G_d(\lambda), G_f(\lambda), G_w(\lambda)\}$, $S \in \mathbb{R}^{n_b \times m_f}$

Outputs: $Q^{(i)}(\lambda)$, $R_f^{(i)}(\lambda)$, $R_w^{(i)}(\lambda)$

1. Compute a minimal left nullspace basis $Q(\lambda)$ of $G(\lambda)$ in (17) and

$$[R_f(\lambda) \ R_w(\lambda)] = Q(\lambda) \begin{bmatrix} G_f(\lambda) & G_w(\lambda) \\ 0 & 0 \end{bmatrix},$$

such that $Q(\lambda)$, $R_f(\lambda)$ and $R_w(\lambda)$ are stable.

2. For $i = 1, \dots, n_b$

2.1 Form $\bar{G}_d^{(i)}(\lambda)$ from the columns $R_{f_j}(\lambda)$ for which $S_{ij} = 0$ and $\bar{G}_f^{(i)}(\lambda)$ from the columns $R_{f_j}(\lambda)$ for which $S_{ij} \neq 0$.

2.2 Apply **Procedure AFD** to the system described by $\{0, \bar{G}_d^{(i)}(\lambda), \bar{G}_f^{(i)}(\lambda), R_w(\lambda)\}$ to obtain the stable filter $\bar{Q}^{(i)}(\lambda)$.

Exit if no solution exists.

2.3 Compute $Q^{(i)}(\lambda) = \bar{Q}^{(i)}(\lambda)Q(\lambda)$, $R_f^{(i)}(\lambda) = \bar{Q}^{(i)}(\lambda)R_f(\lambda)$ and $R_w^{(i)}(\lambda) = \bar{Q}^{(i)}(\lambda)R_w(\lambda)$.

The existence conditions of Theorem 2 are implicitly checked when performing **Procedure AFD** at Step 2.2.

Software Tools

The development of dedicated software tools for the synthesis of fault detection filters must fulfill some general requirements for robust software implementation, but also some requirements specific to the field of fault diagnosis. In what follows, we shortly discuss some of these requirements.

A basic requirement is the use of general, numerically reliable, and computationally efficient numerical approaches as basis for the implementation of all computational functions, to guarantee the solvability of problems under the most general existence conditions of the solutions. Synthesis procedures suitable for robust software implementations are described in the book (Varga 2017).

For beginners, it is important to be able to easily obtain preliminary synthesis results. Therefore, for ease of use, simple and uniform user interfaces are desirable for all synthesis functions. This can be achieved by relying on mean-

ingful default settings for all problem parameters and synthesis options.

For experienced users, an important requirement is to provide an exhaustive set of options to ensure the complete freedom in choosing problem-specific parameters and synthesis options.

The following synthesis options are frequently used: we mention the number of residual signal outputs; stability degree for the poles of the resulting filters or the location of their poles; type of the employed nullspace basis (e.g., minimal proper, full-order observer based); performing least order synthesis, etc.

The *Fault Detection and Isolation Tools* (FDITOOLS) is a publicly available collection of MATLAB *m*-files for the analysis and solution of fault diagnosis problems and has been implemented along the previously formulated requirements. FDITOOLS supports six basic synthesis approaches of linear residual generation filters for both continuous-time and discrete-time LTI systems. The underlying synthesis techniques rely on reliable numerical algorithms developed by the author and are described in Chapters 5–7 of the book (Varga 2017). The functions of the FDITOOLS collection rely on the *Control System Toolbox* (MathWorks 2015, and later releases) and the *Descriptor System Tools* (DSTOOLS) (Varga 2018a). DSTOOLS provides the basic tools for the manipulation of rational TFMs via their descriptor system representations. The version V1.0 of the FDITOOLS collection covers all synthesis procedures described in (Varga 2017) and, additionally, includes several useful analysis functions, as well as functions for an easy setup of synthesis models.

A precursor of FDITOOLS was the Fault Detection Toolbox for MATLAB, a proprietary software of the German Aerospace Center (DLR), developed between 2004 and 2014 (for the status of this toolbox around 2006, see (Varga 2006)).

Recommended Reading

The book (Varga 2017) provides extensive information on the mathematical background of solving synthesis problems of fault detection filters, gives detailed descriptions of the underlying synthesis procedures and contains an extensive list of references to the relevant literature. The numerical aspects of the synthesis procedures are also amply described (a novelty in the fault detection related literature). Additionally, this book addresses the related model detection problematic, a multiple model based approach to solve fault diagnosis problems (e.g., for parametric or multiplicative faults). An extended version of this entry, available in arXiv (Varga 2019b), additionally addresses fault diagnosis problems related to model-matching techniques and provides an extended list of references. For a concise presentation of the descriptor system techniques employed in the synthesis procedures, see the companion article (Varga 2019a).

FDITOOLS is distributed as a free software via the Bitbucket repository <https://bitbucket.org/DSVarga/fditools>. A comprehensive documentation of version V1.0 is available in arXiv (Varga 2018b).

estimation (FE) · Fault-tolerant control · Passive FTC · Reconfigurable control

Fault-Tolerant Control

Ron J. Patton

School of Engineering, University of Hull, Hull, UK

Abstract

A closed-loop control system for an engineering process may have unsatisfactory performance or even instability when faults occur in actuators, sensors, or other process components. Fault-tolerant control (FTC) involves the development and design of special controllers that are capable of tolerating the actuator, sensor, and process faults while still maintaining desirable and robust performance and stability properties. FTC designs involve knowledge of the nature and/or occurrence of faults in the closed-loop system either implicitly or explicitly using methods of fault detection and isolation (FDI), fault detection and diagnosis (FDD), or fault estimation (FE). FTC controllers are reconfigured or restructured using FDI/FDD information so that the effects of the faults are reduced or eliminated within each feedback loop in *active* or *passive* approaches or compensated in each control-loop using FE methods. A non-mathematical outline of the essential features of FTC systems is given with important definitions and a classification of FTC systems into either active/passive approaches with examples of some well-known strategies.

Introduction

The complexity of modern engineering systems has led to strong demands for enhanced control system reliability, safety, and green operation in the presence of even minor anomalies. There is a growing need not only to determine the onset and development of process faults before they become serious but also to adaptively compensate for their effects in the closed-loop system or using hardware redundancy to replace faulty components by duplicate and fault-free alternatives. The title “failure tolerant control” was given by Eterno et al. (1985) working on a reconfigurable flight control study defining the meaning of control system tolerance to failures or faults. The word “failure” is used when a fault is so serious that the system function concerned fails to operate (Isermann 2006). The title failure detection has now been superseded by *fault detection*, e.g., in *fault detection and isolation* (FDI) or *fault detection and diagnosis* (FDD) (Gertler 1998; Chen and Patton 1999; Patton et al. 2000) motivated by studies in the 1980s on this topic (Patton et al. 1989). *Fault-tolerant control* (FTC) began to develop in the early 1990s (Patton 1993) and is now a standard in the literature (Patton 1997; Blanke et al. 2006; Zhang and Jiang 2008), based on the aerospace subject of reconfigurable flight control making use of redundant actuators and sensors (Steinberg 2005; Edwards et al. 2010).

Definitions Relating to Fault-Tolerant Control

FTC is a strategy in control systems architecture and design to ensure that a closed-loop system

can continue acceptable operation in the face of bounded actuator, sensor, or process faults. The goal of FTC design must ensure that the closed-loop system maintains satisfactory stability and acceptable performance during either one or more fault actions. When prescribed stability and closed-loop performance indices are maintained despite the action of faults, the system is said to be “fault tolerant,” and the control scheme that ensures the fault tolerance is the fault-tolerant controller (Patton 1997; Blanke et al. 2006).

Fault modelling is concerned with the representation of the real physical faults and their effects on the system mathematical model. Fault modelling is important to establish how a fault should be detected, isolated, or compensated. The faults illustrated in Fig. 1 act at system locations defined as follows (Chen and Patton 1999):

An *actuator fault* ($f_a(t)$) corresponds to variations of the control input $u(t)$ applied to the controlled system either completely or partially. The complete failure of an actuator means that it produces no actuation regardless of the input applied to it, e.g., as a result of breakage and burnout of wiring. For partial actuator faults, the actuator becomes less effective and provides the plant with only a part of the normal actuation signal.

A sensor is an item of equipment that takes a measurement or observation from the system, e.g., potentiometers, accelerometers, tachometers, pressure gauges, strain gauges, etc.; a *sensor fault* ($f_s(t)$) implies that incorrect

measurements are taken from the real system. This fault can also be subdivided into either a complete or partial sensor fault. When a sensor fails, the measurements no longer correspond to the required physical parameters. For a partial sensor fault the measurements give an inaccurate indication of required physical parameters.

A *process fault* ($f_p(t)$) directly affects the physical system parameters and in turn the input/output properties of the system. Process faults are often termed *component faults*, arising as variations from the structure or parameters used during system modelling, and as such cover a wide class of possible faults, e.g., dirty water having a different heat transfer coefficient compared to when it is clean, or changes in the viscosity of a liquid or components slowly degrading over time through wear and tear, aging, or environmental effects.

Architectures and Classification of FTC Schemes

FTC methods are classified according to whether they are “passive” or “active,” using fixed or reconfigurable control strategies (Eterno et al. 1985). Various architectures have been proposed for the implementation of FTC schemes, for example, the structure of reconfigurable control based on generalized internal model control (GIMC) has been proposed by Zhou and Ren (2001) and other studies by Niemann and

Fault-Tolerant Control,

with actuator, process, and
sensor faults

Fault-Tolerant Control,
Fig. 2 Scheme of FTC
(Adapted from Blanke
et al. (2006))

Stoustrup (2005). Figure 2 shows a suitable architecture to encompass active and passive FTC methods in which a distinction is made between “execution” and “supervision” levels. The essential differences and requirements between the passive FTC (PFTC) and active FTC (AFTC).

PFTC is based solely on the use of robust control in which potential faults are considered as if they are uncertain signals acting in the closed-loop system. This can be related to the concept of reliable control (Veillette et al. 1992). PFTC requires no online information from the fault diagnosis (FDI/FDD/FE) function about the occurrence or presence of faults and hence it is not by itself an adaptive system and does not involve controller reconfiguration (Šiljak 1980; Patton 1993, 1997). PFTC approach can be used if the time window during which the system remains stabilizable in the presence of a fault is short; see, for example, the problem of the double inverted pendulum (Weng et al. 2007) which is unstable during a loop failure.

AFTC has *two* conceptual steps to provide the system with fault-tolerant capability (Patton 1997; Blanke et al. 2006; Zhang and Jiang 2008; Edwards et al. 2009):

- Equip the system with a mechanism to make it able to detect and isolate (or even estimate) the fault promptly, identify a faulty component, and select the required remedial action in to maintain acceptable operation performance.

With no fault a *baseline controller* attenuates disturbances and ensures good stability and closed-loop tracking performance (Patton 1997), and the diagnostic (FDI/FDD/FE) block recognizes that the closed-loop system is fault-free with no control law change required (supervision level).

- Make use of supervision level information and adapt or reconfigure/restructure the controller parameters so that the required remedial activity can be achieved (execution level).

Figure 3 gives a classification of PFTC and AFTC methods (Patton 1997).

Figure 3 shows that AFTC approaches are divided into two main types of methods: projection-based methods and online automatic controller redesign methods. The latter involves the calculation of new controller parameters following control impairment, i.e., using reconfigurable control. In projection-based methods, a new precomputed control law is selected according to the required controller structure (i.e., depending on the type of isolated fault).

AFTC methods use online-fault accommodation based on unanticipated faults, classified as (Patton 1997):

- (a) Based on offline (pre-computed) control laws
- (b) Online-fault accommodating
- (c) Tolerant to unanticipated faults using FDI/FDD/FE
- (d) Dependent upon use of a baseline controller

Fault-Tolerant Control,
Fig. 3 General
 classification of FTC
 methods

AFTC Examples

One example of AFTC is model-based predictive control (MPC) which uses online computed control redesign. MPC is online-fault accommodating; it does not use an FDI/FDD unit and is not dependent on a baseline controller. MPC has a certain degree of fault tolerance against actuator faults under some conditions even if the faults are not detected. The representation of actuator faults in MPC is relatively natural and straightforward since actuator faults such as jams and slew-rate reductions can be represented by changing the MPC optimization problem constraints. Other faults can be represented by modifying the internal model used by MPC (Maciejowski 1998). The fact that online-fault information is not required means that MPC is an interesting method for flight control reconfiguration as demonstrated by Maciejowski and Jones in the GARTEUR AG 16 project on “fault-tolerant flight control” (Edwards et al. 2010).

Another interesting AFTC example that makes use of the concept of *model-matching* in explicit model following is the so-called pseudo-inverse method (PIM) (Gao and Antsaklis 1992) which requires the nominal or reference closed-loop system matrix to compute the new controller gain after a fault has occurred. The challenges are:

1. Guarantee of stability of the reconfigured closed-loop system

2. Minimization of the time consumed to approach the acceptable matching
3. Achieving perfect matching through use of different control methodologies

Exact model-matching may be too demanding, and some extensions to this approach make use of alternative, approximate (norm-based) model-matching through the computation of the required model-following gain. To relax the matching condition further, Staroswiecki (2005) proposed an *admissible model-matching* approach which was later extended by Tornil et al. (2010) using D-region pole assignment. The PIM approach requires an FDI/FDD/FE mechanism and is online-fault accommodating only in terms of *a priori* anticipated faults. This limits the practical value of this approach.

As a third example, feedback linearization can be used to compensate for nonlinear dynamic effects while also implementing control law reconfiguration or restructure. In flight control an aileron actuator fault will cause a strong coupling between the lateral and longitudinal aircraft dynamics. Feedback linearization is an established technique in flight control (Ochi and Kanai 1991). The faults are identified indirectly by estimating aircraft flight parameters online, e.g., using a recursive least-squares algorithm to update the FTC.

Hence, a AFTC system provides fault tolerance either by selecting a precomputed control law (*projection-based*) (Maybeck and Stevens 1991; Rauch 1995; Boskovic and Mehra 1999) or by synthesizing a new control strategy online (*online controller redesign*) (Ahmed-Zaid et al. 1991; Richter et al. 2007; Zou and Kumar 2011; Efimov et al. 2012).

Another widely studied AFTC method is the *estimation and compensation approach*, where a fault compensation input is superimposed on the nominal control input (Noura et al. 2000; Boskovic and Mehra 2002; Zhang et al. 2004; Sami and Patton 2013). There is a growing interest in robust FE methods based on sliding mode estimation (Edwards et al. 2000) and augmented observer methods (Gao and Ding 2007; Jiang et al. 2006; Sami and Patton 2013).

An important development of this approach is the so-called fault hiding strategy which is centered on achieving FTC loop goals such that the nominal control loop remains unchanged through the use of virtual actuators or virtual sensors (Blanke et al. 2006; Sami and Patton 2013). Fault hiding makes use of the difference between the nominal and faulty system state to changes in the system dynamics such that the required control objectives are continuously achieved even if a fault occurs. In the sensor fault case, the effect of the fault is hidden from the input of the controller. However, actuator faults are compensated by the effect of the fault (Lunze and Steffen 2006; Richter et al. 2007; Ponsart et al. 2010; Sami and Patton 2013) in which it is assumed that the FDI/FDD or FE scheme is available. The virtual actuator/sensor FTC can be good practical value if FDI/FDD/FE robustness can be demonstrated.

Traditional adaptive control methods that automatically adapt controller parameters to system changes can be used in a special application of AFTC, potentially removing the need for FDI/FDD and controller redesign steps (Tang et al. 2004; Zou and Kumar 2011) but possibly using the FE function. Adaptive control is suitable for FTC on plants that have slowly

varying parameters and can tolerate actuator and process faults. Sensor faults are not tolerated well as the controller parameters must adapt according to the faulty measurements, causing incorrect closed-loop system operation; the FDI/FDD/FE unit is required for such cases.

Summary and Future Directions

FTC is now a significant subject in control systems science with many quite significant application studies, particularly since the new millennium. Most of the applications are within the flight control field with studies such as the GARTEUR AG16 project “Fault-Tolerant Flight Control” (Edwards et al. 2010). As a very complex engineering-led and mathematically focused subject, it is important that FTC remains application-driven to keep the theoretical concepts moving in the right directions and satisfying end-user needs. The original requirement for FTC in safety-critical systems has now widened to encompass a good range of fault-tolerance requirements involving energy and economy, e.g., for greener aircraft and for FTC in renewable energy.

Faults and modelling uncertainties as well as endogenous disturbances have potentially competing effects on the control system performance and stability. This is the *robustness problem in FTC* which is beyond the scope of this article. The FTC system provides a degree of tolerance to closed-loop systems faults and it is also subject to the effects of modelling uncertainty arising from the reality that all engineering systems are nonlinear and can even have complex dynamics. For example, consider the PFTC approach relying on robustness principles – as a more complex extension to robust control. PFTC design requires the closed-loop system to be insensitive to faults as well as modelling uncertainties. This requires the use of multi-objective optimization methods e.g., using linear matrix inequalities (LMI), as well as methods of accounting for dynamical system parametric variations, e.g., linear parameter varying (LPV) system structures, Takagi-Sugeno, or sliding mode methods.

Feedback Linearization of Nonlinear Systems

Arthur J. Krener
Department of Applied Mathematics, Naval
Postgraduate School, Monterey, CA, USA

Abstract

Effective methods exist for the control of linear systems but this is less true for nonlinear systems. Therefore, it is very useful if a nonlinear system can be transformed into or approximated by a linear system. Linearity is not invariant under nonlinear changes of state coordinates and nonlinear state feedback. Therefore, it may be possible to convert a nonlinear system into a linear one via these transformations. This is called feedback linearization. This entry surveys feedback linearization and related topics.

Involution distribution · Lie derivative

Introduction

A controlled linear dynamics is of the form

$$\dot{x} = Fx + Gu \quad (1)$$

where the state $x \in \mathbb{R}^n$ and the control $u \in \mathbb{R}^m$.
A controlled nonlinear dynamics is of the form

$$\dot{x} = f(x, u) \quad (2)$$

where x , u have the same dimensions but may be local coordinates on some manifolds $\mathcal{X}$, $\mathcal{U}$. Frequently, the dynamics is affine in the control, i.e.,

$$\dot{x} = f(x) + g(x)u \quad (3)$$

where $f(x) \in \mathbb{R}^{n \times 1}$ is a vector field and $g(x) = [g^1(x), \dots, g^m(x)] \in \mathbb{R}^{n \times m}$ is a matrix field.

Linear dynamics are much easier to analyze and control than nonlinear dynamics. For example, to globally stabilize the linear dynamics (1), all we need to do is to find a linear feedback law $u = Kx$ such that all the eigenvalues of $F + GK$ are in the open left half plane. Finding a feedback law $u = \kappa(x)$ to globally stabilize the nonlinear dynamics is very difficult and frequently impossible. Therefore, finding techniques to linearize nonlinear dynamics has been a goal for several centuries.

The simplest example of a linearization technique is to approximate a nonlinear dynamics around a critical point by its first-order terms. Suppose x^0 , u^0 is an operating point for the nonlinear dynamics (2), that is, $f(x^0, u^0) = 0$. Define displacement variables $z = x - x^0$ and $v = u - u^0$, and assuming $f(x, u)$ is smooth around this operating point, expand (2) to first order

$$\dot{z} = \frac{\partial f}{\partial x}(x^0, u^0)z + \frac{\partial f}{\partial u}(x^0, u^0)v + O(z, v)^2 \quad (4)$$

Ignoring the higher order terms, we get a linear dynamics (1) where

$$F = \frac{\partial f}{\partial x}(x^0, u^0), \quad G = \frac{\partial f}{\partial u}(x^0, u^0)$$

This simple technique works very well in many cases and is the basis for many engineering designs. For example, if the linear feedback $v = Kz$ puts all the eigenvalues of $F + GK$ in the left half plane, then the affine feedback $u = u^0 + K(x - x^0)$ makes the closed-loop dynamics locally asymptotically stable around x^0 . So, one way to linearize a nonlinear dynamics is to approximate it by a linear dynamics.

The other way to linearize is by a nonlinear change of state coordinates and a nonlinear state feedback because linearity is not invariant under these transformations. To see this, suppose we have a controlled linear dynamics (1) and we make the nonlinear change of state coordinates $z = \phi(x)$ and nonlinear feedback $u = \gamma(z, v)$. We assume that these transformations are invertible from some neighborhood of $x^0 = 0, u^0 = 0$ to some neighborhood of z^0, v^0 , and the inverse maps are

$$\begin{aligned} \psi(\phi(x)) &= x, & \phi(\psi(z)) &= z \\ \kappa(\psi(z), \gamma(z, v)) &= v, & \gamma(\phi(x), \kappa(x, u)) &= u \end{aligned}$$

then (1) becomes

$$\begin{aligned} \dot{z} &= \frac{\partial \phi}{\partial x}(x) (Fx + Gu) \\ &= \frac{\partial \phi}{\partial x}(\psi(z)) (F\psi(z) + G\gamma(z, v)) \end{aligned}$$

which is a controlled nonlinear dynamics (2). This raises the question asked by Brockett (1978), when is a controlled nonlinear dynamics a change of coordinate and feedback away from a controlled linear dynamics?

Linearization of a Smooth Vector Field

Let us start by addressing an apparently simpler question that was first considered by Poincaré. Given an uncontrolled nonlinear dynamics around a critical point, say $x^0 = 0$,

$$\dot{x} = f(x), \quad f(0) = 0,$$

find a smooth local change of coordinates

$$z = \phi(x), \quad \phi(0) = 0$$

which transforms it into an uncontrolled linear dynamics.

$$\dot{z} = Fz.$$

This question is apparently simpler, but as we shall see in the next section, the corresponding question for a controlled nonlinear dynamics that is affine in the control is actually easier to answer.

Without loss of generality, we can restrict our attention to changes of coordinates which carry $x^0 = 0$ to $z^0 = 0$ and whose Jacobian at this point is the identity, i.e.,

$$z = x + O(x^2)$$

then

$$F = \frac{\partial f}{\partial x}(0).$$

Poincaré's formal solution to this problem was to expand the vector field and the desired change of coordinates in a power series,

$$\begin{aligned} \dot{x} &= Fx + f^{[2]}(x) + O(x^3) \\ z &= x - \phi^{[2]}(x) \end{aligned}$$

where $f^{[2]}, \phi^{[2]}$ are n -dimensional vector fields, whose entries are homogeneous polynomials of degree 2 in x . A straightforward calculation yields

$$\dot{z} = Fz + f^{[2]}(x) - [Fx, \phi^{[2]}(x)] + O(x)^3$$

where the Lie bracket of two vector fields $f(x)$, $g(x)$ is the new vector field defined by

$$[f(x), g(x)] = \frac{\partial g}{\partial x}(x)f(x) - \frac{\partial f}{\partial x}(x)g(x).$$

Hence, $\phi^{[2]}(x)$ must satisfy the so-called homological equation (Arnol'd 1983)

$$[Fx, \phi^{[2]}(x)] = f^{[2]}(x).$$

This is a linear equation from the space of quadratic vector fields to the space of quadratic vector fields. The quadratic n -dimensional vector fields form a vector space of dimension n times $n + 1$ choose 2.

Poincaré showed that the eigenvalues of the linear map

$$\phi^{[2]}(x) \mapsto [Fx, \phi^{[2]}(x)] \quad (5)$$

are $\lambda_i + \lambda_j - \lambda_k$ where $\lambda_i, \lambda_j, \lambda_k$ are eigenvalues of F . If none of these expressions are zero, then the operator (5) is invertible. A degree two resonance occurs when $\lambda_i + \lambda_j - \lambda_k = 0$ and then the homological equation is not solvable for all $f^{[2]}(x)$.

Suppose a change of coordinates exists that linearizes the vector field up to degree r . In the new coordinates, the vector field is of the form

$$\dot{x} = Fx + f^{[r]}(x) + O(x)^{r+1}.$$

We seek a change of coordinates of the form

$$z = x - \phi^{[r]}(x)$$

to cancel the degree r terms, i.e., we seek a solution of the r th degree homological equation,

$$[Fx, \phi^{[r]}(x)] = f^{[r]}(x).$$

A degree r resonance occurs if

$$\lambda_{i_1} + \dots + \lambda_{i_r} - \lambda_k = 0.$$

If there is no resonance of degree r , then the degree r homological equation is uniquely solvable for every $f^{[r]}(x)$.

When there are no resonances of any degree, then the convergence of the formal power series solution is delicate. We refer the reader to Arnol'd (1983) for the details.

Linearization of a Controlled Dynamics by Change of State Coordinates

Given a controlled affine dynamics (3) when does there exist a smooth local change of coordinates

$$z = \phi(x), \quad 0 = \phi(0)$$

transforming it to

$$\dot{z} = Fz + Gu$$

where

$$F = \frac{\partial f}{\partial x}(0), \quad G = g(0)$$

This is an easier question to answer than that of Poincaré.

The controlled affine dynamics (3) is said to have well-defined controllability (Kronecker) indices if there exists a reordering of $g^1(x), \dots, g^m(x)$ and integers $r_1 \geq r_2 \geq \dots \geq r_m \geq 0$ such that $r_1 + \dots + r_m = n$, and the vector fields

$$\{ad^k(f)g^j : j = 1, \dots, m, k = 0, \dots, r_j - 1\}$$

are linearly independent at each x where g^i denotes the i th column of g and

$$ad^0(f)g^i = g^i, \quad ad^k(f)g^i = [f, ad^{k-1}(f)g^i].$$

If there are several sets of indices that satisfy this definition, then the controllability indices are the smallest in the lexicographic ordering.

A necessary and sufficient condition is that

$$[\text{ad}^k(f)g^i, \text{ad}^l(f)g^j] = 0$$

for $k = 0, \dots, n-1$, $l = 0, \dots, n$

The proof of this theorem is straightforward. Under a change of state coordinates, the vector fields and their Lie brackets are transformed by the Jacobian of the coordinate change. Trivially for linear systems,

$$\begin{aligned} \text{ad}^k(Fx)G^i &= (-1)^k F^k G \\ [\text{ad}^k(Fx)G^i, \text{ad}^l(Fx)G^j] &= 0. \end{aligned}$$

Feedback Linearization

We turn to a question posed and partially answered by Brockett (1978). Given a system affine in the m -dimensional control

$$\dot{x} = f(x) + g(x)u,$$

find a smooth local change of coordinates and smooth feedback

$$z = \phi(x), \quad u = \alpha(x) + \beta(x)v$$

transforming it to

$$\dot{z} = Fz + Gv$$

Brockett solved this problem under the assumptions that β is a constant and the control is a scalar, $m = 1$. The more general question for $\beta(x)$ and arbitrary m was solved in different ways by Korobov (1979), Jakubczyk and Respondek (1980), Sommer (1980), Hunt and Su (1981), Su (1982), and Hunt et al. (1983).

We describe the solution when $m = 1$. If the pair F, G is controllable, then there exist an H such that

$$\begin{aligned} HF^{k-1}G &= 0 & k &= 1, \dots, n-1 \\ HF^{n-1}G &= 1 \end{aligned}$$

If the nonlinear system is feedback linearizable, then there exists a function $h(x) = H\phi(x)$ such that

$$\begin{aligned} L_{\text{ad}^{k-1}(f)}g h &= 0 & k &= 1, \dots, n-1 \\ L_{\text{ad}^{n-1}(f)}g h &\neq 0 \end{aligned}$$

where the Lie derivative of a function h by a vector field g is given by

$$L_g h = \frac{\partial h}{\partial x} g$$

This is a system of first-order PDEs, and the solvability conditions are given by the classical Frobenius theorem, namely, that

$$\{g, \dots, \text{ad}^{n-2}(f)g\}$$

is involutive, i.e., its span is closed under Lie bracket.

For controllable systems, this is a necessary and sufficient condition. The controllability condition is that $\{g, \dots, \text{ad}^{n-1}(f)g\}$ spans x space.

Suppose $m = 2$ and the system has controllability (Kronecker) indices $r_1 \geq r_2$. Such a system is feedback linearizable iff

$$\{g^1, g^2, \dots, \text{ad}^{r_1-2}(f)g^1, \text{ad}^{r_1-2}(f)g^2\}$$

is involutive for $i = 1, 2$. Another way of putting is that the distribution spanned by the first through r th rows of the following matrix must be involutive for $r = r_i - 1$, $i = 1, 2$. This is equivalent to the distribution spanned by the first through r th rows of the following matrix being involutive for all $r = 1, \dots, r_1$.

$$\begin{bmatrix} g^1 & g^2 \\ \text{ad}(f)g & \text{ad}(f)g^2 \\ \vdots & \vdots \\ \text{ad}^{r_2-2}(f)g^1 & \text{ad}^{r_2-2}(f)g^2 \\ \text{ad}^{r_2-1}(f)g^1 & \text{ad}^{r_2-1}(f)g^2 \\ \vdots & \vdots \\ \text{ad}^{r_1-2}(f)g^1 & \vdots \\ \text{ad}^{r_1-1}(f)g^1 & \vdots \end{bmatrix}$$

One might ask if it is possible to use dynamic feedback to linearize a system that is not linearizable by static feedback. Suppose we treat one of the controls u_j as a state and let its derivative be a new control,

$$\dot{u}_j = \bar{u}_j$$

can the resulting system be linearized by state feedback and change of state coordinates? Loosely speaking, the effect of adding such an integrator to the j th control is to shift the j th column of the above matrix down by one row. This changes the distribution spanned by the first through r th rows of the above matrix and might make it involutive. A scalar input system $m = 1$ that is linearizable by dynamic state feedback is also linearizable by static state feedback. There are multi-input systems $m > 1$ that are dynamically linearizable but not statically linearizable (Charlet et al. 1989, 1991).

The generic system is not feedback linearizable, but mechanical systems with one actuator for each degree of freedom typically are feedback linearizable. This fact had been used in many applications, e.g., robotics, before the concept of feedback linearization.

One should not lose sight of the fact that stabilization, model-matching, or some other performance criterion is typically the goal of controller design. Linearization is a means to the goal. We linearize because we know how to meet the performance goal for linear systems.

Even when the system is linearizable, finding the linearizing coordinates and feedback can be a nontrivial task. Mechanical systems are the exception as the linearizing coordinates are usually the generalized positions. Since the $ad^{k-1}(f)g$ for $k = 1, \dots, n-1$ are characteristic directions of the PDE for h , the general solutions of the ODE's

$$\dot{x} = ad^{k-1}(f)g(x)$$

can be used to construct the solution (Blankenship and Quadrat 1984). The Gardner-Shadwick (GS) algorithm (1992) is the most efficient method that is known.

Linearization of discrete time systems was treated by Lee et al. (1986). Linearization of discrete time systems around an equilibrium manifold was treated by Barbot et al. (1995) and Jakubczyk (1987). Banaszuk and Hauser have also considered the feedback linearization of the transverse dynamics along a periodic orbit, (Banaszuk and Hauser 1995a, b).

Input–Output Linearization

Feedback linearization as presented above ignores the output of the system but typically one uses the input to control the output. Therefore, one wants to linearize the input–output response of the system rather than the dynamics. This was first treated in Isidori and Krener (1982) and Isidori and Ruberti (1984).

Consider a scalar input, scalar output system of the form

$$\dot{x} = f(x) + g(x)u, \quad y = h(x)$$

The relative degree of the system is the number of integrators between the input and the output. To be more precise, the system is of relative degree $r \geq 1$ if for all x of interest,

$$L_{ad^j(f)g}h(x) = 0 \quad j = 0, \dots, r-2$$

$$L_{ad^{r-1}(f)g}h(x) \neq 0$$

In other words, the control appears first in the r th time derivative of the output. Of course, a system might not have a well-defined relative degree as the r might vary with x .

Rephrasing the result of the previous section, a scalar input nonlinear system is feedback linearizable if there exist an pseudo-output map $h(x)$ such the resulting scalar input, scalar output system has a relative degree equal to the state dimension n .

Assume we have a scalar input, scalar output system with a well-defined relative degree $1 \leq r \leq n$. We can define r partial coordinate functions

$$\zeta_i(x) = (L_f)^{i-1}h(x) \quad i = 1, \dots, r$$

and choose $n - r$ functions $\xi_i(x)$, $i = 1, \dots, n - r$ so that (ζ, ξ) are a full set of coordinates on the state space. Furthermore, it is always possible (Isidori 1995) to choose $\xi_i(x)$ so that

$$L_g \xi_i(x) = 0 \quad i = 1, \dots, n - r$$

In these coordinates, the system is in the normal form

$$\begin{aligned} y &= \zeta_1 \\ \dot{\zeta}_1 &= \zeta_2 \\ &\vdots \\ \dot{\zeta}_{r-1} &= \zeta_r \\ \dot{\zeta}_r &= f_r(\zeta, \xi) + g_r(\zeta, \xi)u \\ \dot{\xi} &= \phi(\zeta, \xi) \end{aligned}$$

The feedback $u = u(\zeta, \xi, v)$ defined by

$$u = \frac{(v - f_r(\zeta, \xi))}{g_r(\zeta, \xi)}$$

transforms the system to

$$\begin{aligned} y &= H\zeta \\ \dot{\zeta} &= F\zeta + Gv \\ \dot{\xi} &= \phi(\zeta, \xi) \end{aligned}$$

where F , G , H are the $r \times r$, $r \times 1$, $1 \times r$ matrices

$$F = \begin{bmatrix} 0 & 1 & 0 & \dots & 0 \\ 0 & 0 & 1 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & 1 \\ 0 & 0 & 0 & \dots & 0 \end{bmatrix} \quad G = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}$$

$$H = [1 \ 0 \ 0 \ \dots \ 0].$$

The system has been transformed into a string of integrators plus additional dynamics that is unobservable from the output.

By suitable choice of additional feedback $v = K\zeta$, one can insure that the poles of $F + GK$ are stable. The stability of the overall system then depends on the stability of the zero dynamics (Byrnes and Isidori 1984, 1988),

$$\dot{\xi} = \phi(0, \xi)$$

If this is stable, then the overall system will be stable. The zero dynamics is so-called because it is the dynamics that results from imposing the constraint $y(t) = 0$ on the system. For this to be satisfied, the initial value must satisfy $\zeta(0) = 0$ and the control must satisfy

$$u(t) = -\frac{f_r(0, \xi(t))}{g_r(0, \xi(t))}$$

Similar results hold in the multiple input, multiple output case, see Isidori (1995) for the details.

Approximate Feedback Linearization

Since so few controlled dynamics are exactly feedback linearizable, Krener (1984) introduced the concept of approximate feedback linearization. The goal is to find a smooth local change of coordinates and a smooth feedback

$$z = \phi(x), \quad u = \alpha(x) + \beta(x)v$$

transforming the affinity controlled dynamics (3) to

$$\dot{z} = Fz + Gv + N(x, u)$$

where the nonlinearity $N(x, u)$ is small in some sense. In the design process, the nonlinearity is ignored, and the controller design is done on the linear model and then transformed back into a controller for the original system.

The power series approach of Poincaré was taken by Krener et al. (1987, 1988, 1991), Krener (1990), and Krener and Maag (1991). See also Kang (1994). It is applicable to dynamics which may not be affine in the control. The controlled nonlinear dynamics (2), the change of coordinates, and the feedback are expanded in

a power series

$$\dot{x} = Fx + Gu + f^{[2]}(x, u) + O(x, u)^3$$

$$z = x - \phi^{[2]}(x)$$

$$v = u - \alpha^{[2]}(x, u)$$

The transformed system is

$$\dot{z} = Fz + Gv + f^{[2]}(x, u)$$

$$- \left[Fx + Gu, \phi^{[2]}(x) \right] + G\alpha^{[2]}(x, u) \\ + O(x, u)^3$$

To eliminate the quadratic terms, one seeks a solution of the degree two homological equations for $\phi^{[2]}$, $\alpha^{[2]}$

$$\left[Fx + Gu, \phi^{[2]}(x) \right] - G\alpha^{[2]}(x, u) = f^{[2]}(x, u)$$

Unlike before, the degree two homological equations are not square. Almost always, the number of unknowns is less than the number of equations. Furthermore, the the mapping

$$\left(\phi^{[2]}(x), \alpha^{[2]}(x, u) \right) \mapsto \left[Fx + Gu, \phi^{[2]}(x) \right] \\ - G\alpha^{[2]}(x, u)$$

is less than full rank. Hence, only an approximate, e.g., a least squares solution, is possible. Krener has written a MATLAB toolbox (<http://www.math.ucdavis.edu/~krener> 1995) to compute term by term solutions to the homological equations. The routine `fh2f_h.m` sequentially computes the least square solutions of the homological equations to arbitrary degree.

Observers with Linearizable Error Dynamics

The dual of linear state feedback is linear input–output injection. Linear input–output injection is

the transformation carrying

$$\dot{x} = Fx + Gu$$

$$y = Hx$$

into

$$\dot{x} = Fx + Bu + Ly + Mu$$

$$y = Hx$$

Linear input–output injection and linear change of state coordinates

$$\dot{x} = Fx + Bu + Ly + Mu$$

$$y = Hx$$

$$z = Tx$$

$$\dot{z} = TFT^{-1}x + TLy + TMu$$

define a group action on the class of linear systems. Of course, output injection is not physically realizable on the original system, but it is realizable on the observer error dynamics.

Nonlinear input–output injection is not well defined independent of the coordinates; input–output injection in one coordinate system does not look like input–output injection in another coordinate system.

If a system

$$\dot{x} = f(x, u), \quad y = h(x)$$

can be transformed by nonlinear changes of state and output coordinates

$$z = \phi(x), \quad w = \gamma(y)$$

to a linear system with nonlinear input–output injection

$$\dot{z} = Fz + Gu + \alpha(y, u)$$

$$w = Hz$$

then the observer

$$\dot{\hat{z}} = (F + LH)\hat{z} + Gu + \alpha(y, u) - Lw$$

has linear error dynamics

$$\begin{aligned}\tilde{z} &= z - \hat{z} \\ \dot{\tilde{z}} &= (F + LH)\tilde{z}\end{aligned}$$

If H, F is detectable, then $F + LH$ can be made Hurwitz, i.e., all its eigenvalues are in the open left half plane.

The case when $\gamma = \text{identity}$, there are no inputs $m = 0$ and one output $p = 1$,

$$\begin{aligned}\dot{x} &= f(x) \\ y &= h(x)\end{aligned}$$

was solved by Krener and Isidori (1983) and Bestle and Zeitz (1983) when the pair H, F defined by

$$\begin{aligned}F &= \frac{\partial f}{\partial x}(0) \\ H &= \frac{\partial h}{\partial x}(0)\end{aligned}$$

is observable.

One seeks a change of coordinates $z = \phi(x)$ so that the system is linear up to output injection

$$\begin{aligned}\dot{z} &= Fz + \alpha(y) \\ y &= Hz\end{aligned}$$

If they exist, the z coordinates satisfy the PDE's

$$L_{ad^{n-k}(f)g}(z_j) = \delta_{k,j}$$

where the vector field $g(x)$ is defined by

$$L_g L_f^{k-1} h = \begin{cases} 0 & 1 \leq k < n \\ 1 & k = n \end{cases}$$

The solvability conditions for these PDE's are that for $1 \leq k < l \leq n - 1$

$$[ad^{k-1}(f)g, ad^{l-1}(f)g] = 0.$$

The general case with γ, m, p arbitrary was solved by Krener and Respondek (1985). The solution is a three-step process. First, one must set up and solve a linear PDE for $\gamma(y)$. The integrability conditions for this PDE involve the vanishing of a pseudo-curvature (Krener 1986). The next two steps are similar to the above. One defines a vector field g^j , $1 \leq j \leq p$ for each output, these define a PDE for the change of coordinates, for which certain integrability conditions must be satisfied. The process is more complicated than feedback linearization and even less likely to be successful so approximate solutions must be sought which we will discuss later in this section. We refer the reader Krener and Respondek (1985) and related work Zeitz (1987) and Xia and Gao (1988a, b, 1989).

Very few systems can be linearized by change of state coordinates and input–output injection, so Krener et al. (1987, 1988, 1991), Krener (1990), and Krener and Maag (1991) sought approximate solutions by the power series approach. Again, the system, the changes of coordinates, and the output injection are expanded in a power series. See the above references for details.

Conclusion

We have surveyed the various ways a nonlinear system can be approximated by a linear system.

Abstract

We consider the simplest design problem for nonlinear systems: the problem of rendering asymptotically stable a given equilibrium by means of feedback. For such a problem, we provide a necessary condition, known as Brockett condition, and a sufficient condition, which relies upon the definition of a class of functions, known as control Lyapunov functions. The theory is illustrated by means of a few examples. In addition we discuss a nonlinear enhancement of the so-called separation principle for stabilization by means of partial state information.

Keywords

Stability · Stabilization · Feedback · Nonlinear systems

Introduction

The problem of feedback stabilization, namely, the problem of designing a feedback control law locally, or globally, asymptotically stabilizing a given equilibrium point, is the simplest design problem for nonlinear systems. If the state of the system is available for feedback, then the problem is referred to as the state feedback stabilization problem, whereas if only part of the state, for example, an output signal, is available for feedback, the problem is referred to as the partial state feedback (or output feedback) stabilization problem. We initially focus on the state feedback stabilization problem which can be formulated as follows.

Consider a nonlinear system described by the equation

$$\dot{x} = F(x, u), \quad (1)$$

where $x(t) \in \mathbb{R}^n$ denotes the state of the system, $u(t) \in \mathbb{R}^m$ denotes the input of the system, and $F : \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}^n$ is a smooth mapping.

Let $x_0 \in \mathbb{R}^n$ be an *achievable* equilibrium, i.e., x_0 is such that there exists a constant $u_0 \in \mathbb{R}^m$ such that $F(x_0, u_0) = 0$. The state feedback stabilization problem consists in finding, if possible, a state feedback control law, described by the equation

$$u = \alpha(x), \quad (2)$$

with $\alpha : \mathbb{R}^n \rightarrow \mathbb{R}^m$, such that the equilibrium x_0 is a locally asymptotically stable equilibrium for the closed-loop system

$$\dot{x} = F(x, \alpha(x)). \quad (3)$$

Alternatively, one could require that the equilibrium be globally asymptotically stable. Note that it is not always possible to *extend* local properties to global properties. For example, for the system described by the equations

$$\dot{x}_1 = x_2(1 - x_1^2), \quad \dot{x}_2 = u,$$

with $x_1(t) \in \mathbb{R}$, $x_2(t) \in \mathbb{R}$, and $u(t) \in \mathbb{R}$, it is not possible to design a feedback law which renders the zero equilibrium globally asymptotically stable.

If only partial information on the state is available, then one has to resort to a dynamic *output* feedback controller, namely, a controller described by equations of the form

$$\dot{\xi} = \beta(\xi, y), \quad u = \alpha(\xi), \quad (4)$$

where $\xi(t) \in \mathbb{R}^v$ describes the state of the controller, $y(t) \in \mathbb{R}^p$ is given by $y = h(x)$, for some mapping $h : \mathbb{R}^n \rightarrow \mathbb{R}^p$, and describes the available information on the state x , and $\beta : \mathbb{R}^v \times \mathbb{R}^p \rightarrow \mathbb{R}^v$ and $\alpha : \mathbb{R}^v \rightarrow \mathbb{R}^m$ are smooth mappings. Within this scenario the stabilization problem boils down to selecting the (nonnegative) integer v (i.e., the order of the controller), a constant $\xi_0 \in \mathbb{R}^v$ and the mappings α and β such that the closed-loop system

$$\dot{x} = F(x, \alpha(x)), \quad \dot{\xi} = \beta(\xi, h(x)), \quad (5)$$

has a locally (or globally) asymptotically stable equilibrium at (x_0, ξ_0) . Alternatively, one may require that the equilibrium (x_0, ξ_0) of the closed-loop system (5) be locally asymptotically stable with a region of attraction that contains a given, user-specified, set.

The rest of the entry is organized as follows. We begin discussing two key results. The first is a necessary condition, due to R.W. Brockett, for continuous stabilizability. This provides an obstruction to the solvability of the problem and can be used to show that, for nonlinear systems, controllability does not imply stabilizability by continuous feedback. The second one is the extension of the Lyapunov direct method to systems with control. The main idea is the introduction of a control version of Lyapunov functions, the *control Lyapunov functions*, which can be used to design stabilizing control laws by means of a *universal formula*. We then describe two classes of systems for which it is possible to construct, with systematic procedures, smooth control laws yielding global asymptotic stability of a given equilibrium: systems in feedback and in feedforward form. There are several other constructive and systematic stabilization methods which have been developed in the last few

decades. Worth mentioning are passivity-based methods and center manifold-based methods.

We conclude the entry describing a nonlinear version of the separation principle for the asymptotic stabilization, by output feedback, of a general class of nonlinear systems.

Preliminary Results

To highlight the difficulties and peculiarities of the nonlinear stabilization problem, we recall some basic facts from linear systems theory and exploit such facts to derive a sufficient condition and a necessary condition. In the case of linear systems, i.e., systems described by the equation $\dot{x} = Ax + Bu$, with $A \in \mathbb{R}^{n \times n}$ and $B \in \mathbb{R}^{n \times m}$, and linear state feedback, i.e., feedback described by the equation $u = Kx$, with $K \in \mathbb{R}^{m \times n}$, the stabilization problem boils down to the problem of placing, in the complex plane, the eigenvalues of the matrix $A + BK$ to the left of the imaginary axis. This problem is solvable if and only if the uncontrollable modes of the system are located, in the complex plane, to the left of the imaginary axis.

The linear theory may be used to provide a simple obstruction to feedback stabilizability and a simple sufficient condition. Let x_0 be an achievable equilibrium with $u_0 = 0$ and note that the linear approximation of the system (1) around x_0 is described by an equation of the form $\dot{x} = Ax + Bu$.

If for any $K \in \mathbb{R}^{m \times n}$ the condition (the notation $\sigma(A)$ denotes the spectrum of the matrix A , i.e., the set of the eigenvalues of A)

$$\sigma(A + BK) \cap C^+ \neq \emptyset \quad (6)$$

holds, then the equilibrium of the nonlinear system cannot be stabilized by any continuously differentiable feedback such that $\alpha(x_0) = 0$. Note however that, if the condition $\alpha(x_0) = 0$ is dropped, the obstruction does not hold: the zero equilibrium of $\dot{x} = x + xu$ is not stabilizable by any continuous feedback such that $\alpha(0) = 0$, yet the feedback $u = -2$ is a (global) stabilizer.

On the contrary, if there exists a K such that

$$\sigma(A + BK) \subset C^-$$

then the feedback $\alpha(x) = K(x - x_0)$ locally asymptotically stabilizes the equilibrium x_0 of the closed-loop system. This fact is often referred to as *the linearization approach*.

The above linear arguments are often inadequate to design feedback stabilizers: a theory for nonlinear feedback has to be developed. However, this theory is much more involved. In particular, it is important to observe that the solvability of the stabilization problem may depend upon the regularity properties of the feedback i.e., of the mapping α . In fact, a given equilibrium of a nonlinear system may be rendered locally asymptotically stable by a continuous feedback, whereas there may be no continuously differentiable feedback achieving the same goal. If the feedback is required to be continuously differentiable, then the problem is often referred to as the *smooth stabilization problem*.

Example To illustrate the role of the regularity properties of the feedback consider the system described by the equations

$$\dot{x}_1 = x_1 - x_2^3, \quad \dot{x}_2 = u,$$

with $x_1(t) \in \mathbb{R}$, $x_2(t) \in \mathbb{R}$, and $u(t) \in \mathbb{R}$, and the equilibrium $x_0 = (0, 0)$. The equilibrium is globally asymptotically stabilized by the continuous feedback

$$\alpha(x) = -x_2 + x_1 + \frac{4}{3}x_1^{\frac{1}{3}} - x_2^3,$$

but it is not stabilizable by any continuously differentiable feedback. Note, in fact, that condition (6) holds.

Brockett Theorem

Brockett's necessary condition, which is far from being sufficient, provides a simple test to rule out the existence of a continuous stabilizer.

Theorem 1 Consider the system (1) and assume $x_0 = 0$ is an achievable equilibrium with $u_0 = 0$.

Assume there exists a continuous stabilizing feedback $u = \alpha(x)$. Then, for each $\varepsilon > 0$ there exists $\delta > 0$ such that, for all y with $\|y\| < \delta$, the equation $y = F(x, u)$ has at least one solution in the set $\|x\| < \varepsilon$, $\|u\| < \varepsilon$.

Theorem 1 can be reformulated as follows. The existence of a continuous stabilizer implies that the image of the mapping $F : \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}^n$ covers a neighborhood of the origin. The obstruction expressed by Theorem 1 is of topological nature: it requires continuity of F and α and time-invariance, that is, the theorem is not applicable if $u = \alpha(x, t)$, i.e., a time-varying feedback is considered.

In the linear case, Brockett condition reduces to the condition

$$\text{rank}[A - \lambda I, B] = n$$

for $\lambda = 0$. This is a necessary, but clearly not sufficient, condition for the stabilizability of $\dot{x} = Ax + Bu$.

Example Consider the kinematic model of a mobile robot given by the equations

$$\begin{aligned} \dot{x} &= \cos \theta v, \\ \dot{y} &= \sin \theta v, \\ \dot{\theta} &= \omega, \end{aligned}$$

where $(x(t), y(t)) \in \mathbb{R}^2$ denotes the Cartesian position of the robot, $\theta(t) \in (-\pi, \pi]$ denotes the robot orientation (with respect to the x -axis), $v(t) \in \mathbb{R}$ is the forward velocity of the robot, and $\omega(t) \in \mathbb{R}$ is its angular velocity. Simple intuitive considerations suggest that the system is controllable, i.e., it is possible to select the forward and angular velocities to drive the robot from any initial position/orientation to any final position/orientation in any given positive time. Nevertheless, the zero equilibrium (and any other equilibrium of the system) is not continuously stabilizable. In fact, the equations

$$y_1 = \cos \theta v, \quad y_2 = \sin \theta v, \quad y_3 = \omega,$$

with $\|(y_1, y_2, y_3)\| < \delta$ and $\|(x, y, \theta)\| < \varepsilon$, $\|(v, \omega)\| < \varepsilon$ are in general not solvable. For

example, if $\varepsilon < \pi/2$ and $y_1 = 0$, $y_2 \neq 0$, $y_3 = 0$, then the unique solution of the first and third equations is $v = 0$ and $\omega = 0$, implying $\sin \theta v = 0$; hence the second equation does not have a solution.

Control Lyapunov Functions

The Lyapunov theory states that the equilibrium x_0 of the system

$$\dot{x} = f(x),$$

with $f : \mathbb{R}^n \rightarrow \mathbb{R}^n$, is locally asymptotically stable if there exists a continuously differentiable function $V : \mathbb{R}^n \rightarrow \mathbb{R}$, called Lyapunov function, and a neighborhood U of x_0 such that $V(x_0) = 0$, $V(x) > 0$, for all $x \in U$ and $x \neq x_0$, and $\frac{\partial V}{\partial x} f(x) < 0$, for all $x \in U$ and $x \neq x_0$.

To apply this idea to the stabilization problem, consider the system (1). If the equilibrium x_0 of $\dot{x} = F(x, u)$ is continuously stabilizable then there must exist a continuously differentiable function V and a neighborhood U of x_0 such that

$$\inf_u \frac{\partial V}{\partial x} F(x, u) < 0,$$

for all $x \in U$ and $x \neq x_0$. This motivates the following definition.

Definition 1 A continuously differentiable function V such that

- $V(x_0) = 0$ and $V(x) > 0$, for all $x \in U$ and $x \neq x_0$, where U is a neighborhood of x_0 ;
- $\inf_u \frac{\partial V}{\partial x} F(x, u) < 0$, for all $x \in U$ and $x \neq x_0$;

is called a *control Lyapunov function*.

By Lyapunov theory, the existence of a continuous stabilizer implies the existence of a con-

trol Lyapunov function. On the other hand, the existence of a control Lyapunov function does not guarantee the existence of a stabilizer. However, in the case of systems affine in the control, i.e., systems described by the equation

$$\dot{x} = f(x) + g(x)u, \quad (7)$$

with $f : \mathbb{R}^n \rightarrow \mathbb{R}^n$ and $g : \mathbb{R}^n \rightarrow \mathbb{R}^{n \times m}$ smooth mappings, very general results can be proven. These have been proven by Z. Artstein, who gave a non-constructive statement, and have been given a constructive form by E.D. Sontag. In particular, for single-input nonlinear systems, the following statement holds.

Theorem 2 Consider the system (7), with $m = 1$, and assume $f(0) = 0$. There exists an almost smooth feedback which globally asymptotically stabilizes the equilibrium $x = 0$ if and only if there exists a positive definite, radially unbounded and smooth function $V(x)$ such that

1. the condition $\frac{\partial V}{\partial x} g(x) = 0$ implies $\frac{\partial V}{\partial x} f(x) < 0$, for all $x \neq 0$;
2. for each $\varepsilon > 0$ there is a $\delta > 0$ such that $\|x\| < \delta$ implies that there is a $|u| < \varepsilon$ such that

$$\frac{\partial V}{\partial x} f(x) + \frac{\partial V}{\partial x} g(x)u < 0.$$

Recall that *almost smooth* means that the feedback $\alpha(x)$ is continuously differentiable, for all $x \in \mathbb{R}^n$ and $x \neq 0$, and it is continuous at $x = 0$. A function $V : \mathbb{R}^n \rightarrow \mathbb{R}$ is radially unbounded if $\lim_{\|x\| \rightarrow \infty} V(x) = \infty$.

Condition 2 is known as the *small control property*, and it is necessary to guarantee continuity of the feedback at $x = 0$. If Conditions 1 and 2 hold then an almost smooth feedback is given by the so-called Sontag's universal formula:

$$\alpha(x) = \begin{cases} 0, & \text{if } \frac{\partial V}{\partial x} g(x) = 0, \\ -\frac{\frac{\partial V}{\partial x} f(x) + \sqrt{(\frac{\partial V}{\partial x} f(x))^2 + (\frac{\partial V}{\partial x} g(x))^4}}{\frac{\partial V}{\partial x} g(x)}, & \text{elsewhere.} \end{cases}$$

Constructive Stabilization

We now introduce two classes of nonlinear systems for which systematic design methods to solve the state feedback stabilization problem are available.

Feedback Systems

Consider a nonlinear system described by equations of the form

$$\dot{x}_1 = f_1(x_1, x_2), \quad \dot{x}_2 = u, \quad (8)$$

with $x_1(t) \in \mathbb{R}^n$, $x_2(t) \in \mathbb{R}$, $u(t) \in \mathbb{R}^n$ and $f_1(0, 0) = 0$. This system belongs to the so-called class of feedback systems for which a sort of reduction principle holds: the zero equilibrium of the system is smoothly stabilizable if the same holds for the *reduced* system $\dot{x}_1 = f_1(x_1, v)$, which is obtained from the first of equations (8) replacing the state variable x_2 with a *virtual control* input v . To show this property, suppose there exist a continuously differentiable function $\alpha_1 : \mathbb{R}^n \rightarrow \mathbb{R}$ and a continuously differentiable and radially unbounded function $V_1 : \mathbb{R}^n \rightarrow \mathbb{R}$ such that $V_1(0) = 0$, $V_1(x_1) > 0$, for all $x_1 \neq 0$, and

$$\frac{\partial V_1}{\partial x_1} f_1(x_1, \alpha_1(x_1)) < 0,$$

for all $x_1 \neq 0$, i.e., the zero equilibrium of the system $\dot{x}_1 = f_1(x_1, v)$ is globally asymptotically stabilizable.

Consider now the function

$$V(x_1, x_2) = V_1(x_1) + \frac{1}{2} (x_2 - \alpha_1(x_1))^2,$$

which is radially unbounded and such that $V(0, 0) = 0$ and $V(x_1, x_2) > 0$ for all non-zero (x_1, x_2) , and note that

$$\begin{aligned} \dot{V} &= \frac{\partial V_1}{\partial x_1} f_1(x_1, x_2) \\ &\quad + (x_2 - \alpha_1(x_1))(u + \Delta_1(x_1, x_2)) \\ &= \frac{\partial V_1}{\partial x_1} f_1(x_1, \alpha_1(x_1)) \\ &\quad + (x_2 - \alpha_1(x_1))(u + \Delta_2(x_1, x_2)), \end{aligned}$$

for some continuously differentiable mappings Δ_1 and Δ_2 , which exist by Hadamard's Lemma. As a result, the feedback

$$\alpha(x_1, x_2) = -\Delta_2(x_1, x_2) - k(x_2 - \alpha_1(x_1)),$$

with $k > 0$, yields $\dot{V} < 0$ for all non-zero (x_1, x_2) ; hence the feedback is a continuously differentiable stabilizer for the zero equilibrium of the system (8). Note, finally, that the function V is a control Lyapunov for the system (8); hence Sontag's formula can be also used to construct a stabilizer.

The result discussed above is at the basis of the so-called *backstepping* technique for recursive stabilization of systems described, for example, by equations of the form

$$\begin{aligned} \dot{x}_1 &= x_2 + \varphi_1(x_1), \\ \dot{x}_2 &= x_3 + \varphi_2(x_1, x_2), \\ \dot{x}_3 &= x_4 + \varphi_3(x_1, x_2, x_3), \\ &\vdots \\ \dot{x}_n &= u + \varphi_n(x_1, \dots, x_n), \end{aligned}$$

with $x_i(t) \in \mathbb{R}$, for all $i \in [1, \dots, n]$, and φ_i smooth mappings such that $\varphi_i(0) = 0$, for all $i \in [1, \dots, n]$.

Feedforward Systems

Consider a nonlinear system described by equations of the form

$$\dot{x}_1 = f_1(x_2), \quad \dot{x}_2 = f_2(x_2) + g_2(x_2)u, \quad (9)$$

with $x_1(t) \in \mathbb{R}$, $x_2(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}$, $f_1(0) = 0$ and $f_2(0) = 0$. This system belongs to the so-called class of feedforward systems for which, similarly to feedback systems, a sort of reduction principle holds: the zero equilibrium of the system is smoothly stabilizable if the zero equilibrium of the *reduced* system $\dot{x}_2 = f_2(x_2)$ is globally asymptotically stable and some additional structural assumption holds. To show this property, suppose that there exists a continuously differentiable and radially unbounded function $V_2 : \mathbb{R}^n \rightarrow \mathbb{R}$ such that $V_2(0) = 0$, $V_2(x_2) > 0$, for all $x_2 \neq 0$, and

$$\frac{\partial V_2}{\partial x_2} f_2(x_2) < 0,$$

for all $x_2 \neq 0$. Suppose, in addition, that there exists a continuously differentiable mapping $M(x_2)$ such that

$$f_1(x_2) - \frac{\partial M}{\partial x_2} f_2(x_2) = 0,$$

$M(0) = 0$ and $\left. \frac{\partial M}{\partial x_2} \right|_{x_2=0} \neq 0$. Existence of such a mapping is guaranteed, for example, by asymptotic stability of the linearization of the system $\dot{x}_2 = f_2(x_2)$ around the origin and controllability of the linearization of the system (9) around the origin.

Consider now the function

$$V(x_1, x_2) = \frac{1}{2} (x_1 - M(x_2))^2 + V_2(x_2),$$

which is radially unbounded and such that $V(0, 0) = 0$ and $V(x_1, x_2) > 0$ for all non-zero (x_1, x_2) , and note that

$$\begin{aligned} \dot{V} &= -(x_1 - M(x_2)) \frac{\partial M}{\partial x_2} g_2(x_2) u \\ &\quad + \frac{\partial V_2}{\partial x_2} f_2(x_2) + \frac{\partial V_2}{\partial x_2} g_2(x_2) u \\ &= \frac{\partial V_2}{\partial x_2} f_2(x_2) + \\ &\quad \left(\frac{\partial V_2}{\partial x_2} - (x_1 - M(x_2)) \frac{\partial M}{\partial x_2} \right) g_2(x_2) u. \end{aligned}$$

As a result, the feedback

$$\begin{aligned} \alpha(x_1, x_2) \\ = -k \left(\frac{\partial V_2}{\partial x_2} - (x_1 - M(x_2)) \frac{\partial M}{\partial x_2} \right) g_2(x_2), \end{aligned}$$

with $k > 0$, yields $\dot{V} < 0$ for all non-zero (x_1, x_2) ; hence the feedback is a continuously differentiable stabilizer for the zero equilibrium of the system (9). Note, finally, that the function V is a control Lyapunov for the system (9); hence

Sontag's formula can be also used to construct a stabilizer.

The result discussed above is at the basis of the so-called forwarding technique for recursive stabilization of systems described, for example, by equations of the form

$$\begin{aligned} \dot{x}_1 &= \varphi_1(x_2, \dots, x_n), \\ \dot{x}_2 &= \varphi_2(x_3, \dots, x_n), \\ &\vdots \\ \dot{x}_{n-1} &= \varphi_{n-1}(x_n), \\ \dot{x}_n &= u, \end{aligned}$$

with $x_i(t) \in \mathbb{R}$ for all $i \in [1, \dots, n]$, and φ_i smooth mappings such that $\varphi_i(0) = 0$, for all $i \in [1, \dots, n]$.

Stabilization via Output Feedback

In the previous sections, we have studied the stabilization problem for nonlinear systems under the assumption that the whole state is available for feedback. This requires the on-line measurement of the state vector x , which may pose a severe constraint in applications. This observation motivates the study of the much more challenging, but more realistic, problem of stabilization with partial state information. This problem requires the introduction of a specific notion of observability. Note that for nonlinear systems, it is possible to define several, nonequivalent, observability notions.

Similarly to section “Control Lyapunov Functions,” we focus on the class of systems affine in the control, i.e., systems described by equations of the form

$$\begin{aligned} \dot{x} &= f(x) + g(x)u, \\ y &= h(x), \end{aligned} \tag{10}$$

with $f : \mathbb{R}^n \rightarrow \mathbb{R}^n$, $g : \mathbb{R}^n \rightarrow \mathbb{R}^{n \times m}$, and $h : \mathbb{R}^n \rightarrow \mathbb{R}^p$ smooth mappings. This is precisely the class of systems in equation (7) with the addition of the *output map* h , i.e., a map which describes the information that is available for feedback. In addition we assume, to simplify the notation, that

$m = 1$ and $p = 1$: the system is single-input, single-output.

To define the observability notion of interest, consider the sequence of mappings

$$\begin{aligned}\phi_0(x) &= h(x), \\ \phi_1(x, v_0) &= \frac{\partial \phi_0}{\partial x} [f(x) + g(x)v_0], \\ \phi_2(x, v_0, v_1) &= \frac{\partial \phi_1}{\partial x} [f(x) + g(x)v_0] \\ &\quad + \frac{\partial \phi_1}{\partial v_0} v_1, \\ &\dots \\ \phi_k(x, v_0, v_1, \dots, v_{k-1}) &= \frac{\partial \phi_{k-1}}{\partial x} [f(x) + g(x)v_0] \\ &\quad + \sum_{i=0}^{k-2} \frac{\partial \phi_{k-1}}{\partial v_i} v_{i+1},\end{aligned}\quad (11)$$

with $k \leq n$. Note that, if $u(t)$ is of class C^{k-1} then

$$y^{(k)}(t) = \phi_k(x(t), u(t), \dots, u^{(k-1)}(t)),$$

where the notation $y^{(k)}(t)$, with k positive integer, is used to denote the k -th order derivative of the function $y(t)$, provided it exists. The mappings ϕ_0 to ϕ_{n-1} can be collected into a unique mapping $\Phi : \mathbb{R}^n \times \mathbb{R}^{n-1} \rightarrow \mathbb{R}^n$ defined as

$$\Phi(x, v_0, v_1, \dots, v_{n-2}) = \begin{bmatrix} \phi_0(x) \\ \phi_1(x, v_0) \\ \vdots \\ \phi_{n-1}(x, v_0, v_1, \dots, v_{n-2}) \end{bmatrix}.$$

The mapping Φ is, by construction, such that

$$\begin{aligned}\Phi(x(t), u(t), \dot{u}(t), \dots, u^{(n-2)}(t)) \\ = [y(t) \ \dot{y}(t) \ \dots \ y^{(n-1)}(t)]^T,\end{aligned}$$

for any t in which the indicated signals exist. As a consequence, if the mapping Φ is such that, as

some point $(\bar{x}, \bar{v})$, where $\bar{v} = [\bar{v}_0 \ \bar{v}_1 \ \dots \ \bar{v}_{n-2}]^T$,

$$\text{rank} \frac{\partial \Phi}{\partial x}(\bar{x}, \bar{v}) = n, \quad (12)$$

then, by the Implicit Function Theorem, there exists locally around $(\bar{x}, \bar{v})$ a smooth mapping $\Psi : \mathbb{R}^n \times \mathbb{R}^{n-1} \rightarrow \mathbb{R}^n$ such that

$$\omega = \Phi(\Psi(\omega, v), v),$$

i.e., the mapping Ψ is the *inverse* of Φ , parameterized by v . We conclude the discussion noting that if, at a certain time $\bar{t}$, $\bar{x} = x(\bar{t})$ and $\bar{v} = [u(\bar{t}) \ \dot{u}(\bar{t}) \ \dots \ u^{(n-2)}(\bar{t})]^T$ are such that the rank condition (12) holds then the mapping Ψ can be used to reconstruct the state of the system from measurements of the input, and its derivatives, and the output and its derivatives, for all t in a neighborhood of $\bar{t}$: $x(t) = \Psi(\omega(t), v(t))$, for all t in a neighborhood of $\bar{t}$, where

$$\begin{aligned}v(t) &= [u(t) \ \dot{u}(t) \ \dots \ u^{(n-2)}(t)]^T, \\ \omega(t) &= [y(t) \ \dot{y}(t) \ \dots \ y^{(n-1)}(t)]^T.\end{aligned}\quad (13)$$

This property is a local property: to derive a property which allows a global reconstruction of the state, we need to impose additional conditions.

Definition 2 Consider the system (10) with $m = p = 1$. The system is said to be *uniformly observable* if the following conditions hold.

- (i) The mapping $H : \mathbb{R}^n \rightarrow \mathbb{R}^n$ defined as (the functions $L_f^i h$, with i nonnegative integer, are defined as $L_f h(x) = L_f^1 h(x) = \frac{\partial h}{\partial x} f(x)$ and, recursively, as $L_f^{i+1} h(x) = L_f(L_f^i h(x))$)

$$H(x) = \begin{bmatrix} h(x) \\ L_f h(x) \\ \vdots \\ L_f^{n-1} h(x) \end{bmatrix}$$

is a global diffeomorphism.

- (ii) The rank condition (12) holds for all $(x, v) \in \mathbb{R}^n \times \mathbb{R}^{n-1}$.

The notion of uniform observability allows *performing* a global reconstruction of the state, i.e., it makes sure that the identities

$$\omega = \Phi(\Psi(\omega, v), v), \quad x = \Psi(\Phi(x, v), v),$$

hold for all x, v , and ω . In principle this property may be used in an output feedback control architecture obtained implementing a stabilizing state feedback $u = \alpha(x)$ as $u = \alpha(\Psi(\omega, v))$, with v and ω as given in (13). This implementation is however not possible, since it gives an implicit definition of u and requires the exact differentiation of the input and output signals.

To circumvent these difficulties one needs to follow a somewhat longer path, as described hereafter. In addition, the global asymptotic stability requirement should be replaced by a less ambitious, yet practically meaningful, requirement: semi-global asymptotic stability. This requirement can be formalized as follows.

Definition 3 The equilibrium x_0 of the system (1), or (7), is said to be semi-globally asymptotically stabilizable if, for each compact set $\mathcal{K} \subset \mathbb{R}^n$ such that $x_0 \in \text{int } \mathcal{K}$, where $\text{int } \mathcal{K}$ is the set of all interior points of $\mathcal{K}$, there exists a feedback control law, possibly depending on $\mathcal{K}$, such that the equilibrium x_0 is a locally asymptotically stable equilibrium of the closed-loop system, and for any $x(0) \in \mathcal{K}$ one has $\lim_{t \rightarrow \infty} x(t) = x_0$.

To bypass the need for the derivatives of the input signal, consider the extended system

$$\begin{aligned} \dot{x} &= f(x) + g(x)v_0, & \dot{v}_0 &= v_1, \\ \dot{v}_1 &= v_2, & \dots & \dot{v}_{n-1} = \tilde{u}. \end{aligned} \quad (14)$$

Note that, as described in section the “[Feedback Systems](#),” if the equilibrium $x_0 = 0$ of the system $\dot{x} = f(x) + g(x)u$ is globally asymptotically stabilizable by a (smooth) feedback $u = \alpha(x)$, then there exists a smooth state feedback $\tilde{u} = \tilde{\alpha}(x, v_0, v_1, \dots, v_{n-1})$ which globally asymptotically stabilizes the zero equilibrium of the system (14). In the feedback $\tilde{\alpha}$ one can replace x

with $\psi(\omega, v)$, thus yielding a feedback of the measurable part of the state of the system (14) and of the output y and its derivatives. Note that if $\omega(t) = [y(t) \ \dot{y}(t) \ \dots \ y^{(n-1)}(t)]^T$ then the feedback $\tilde{u} = \tilde{\alpha}(\psi(\omega, v), v_0, v_1, \dots, v_{n-1})$ globally asymptotically stabilizes the zero equilibrium of the system (14).

To avoid the computation of the time derivatives of y we exploit the uniform observability property, which implies that the auxiliary system

$$\begin{aligned} \dot{\eta}_0 &= \eta_1, \\ \dot{\eta}_1 &= \eta_2, \\ &\vdots \\ \dot{\eta}_{n-1} &= \phi_n(\psi(\eta, v), v_0, v_1, \dots, v_{n-1}), \end{aligned} \quad (15)$$

with $\eta = [\eta_0 \ \eta_1 \ \dots \ \eta_{n-1}]^T$, has the property of reproducing $y(t)$ and its derivatives up to $y^{(n-1)}(t)$ if properly initialized. This initialization is not feasible, since it requires the knowledge of the derivative of the output at $t = 0$. Nevertheless, the auxiliary system (15) can be modified to provide an *estimate* of y and its derivatives. The modification is obtained adding a linear correction term yielding the system

$$\begin{aligned} \dot{\eta}_0 &= \eta_1 + L \ c_{n-1}(y - \eta_0), \\ \dot{\eta}_1 &= \eta_2 + L^2 \ c_{n-2}(y - \eta_0), \\ &\vdots \\ \dot{\eta}_{n-1} &= \phi_n(\psi(\eta, v), v_0, v_1, \dots, v_{n-1}) \\ &\quad + L^n \ c_0(y - \eta_0), \end{aligned} \quad (16)$$

with $L > 0$ and the coefficients $c_0, \dots, c_{n-1}$ such that all roots of the polynomial $\lambda^n + c_{n-1}\lambda^{n-1} + \dots + c_1\lambda + c_0$ are in C^- . The system (16) has the ability to provide asymptotic estimates of y and its derivatives up to $y^{(n-1)}$ provided these are bounded and the gain L is selected sufficiently large, i.e., the system (16) is a *semi-global* observer of y and its derivatives up to $y^{(n-1)}$.

The closed-loop system obtained using the feedback law $\tilde{u} = \tilde{\alpha}(\psi(\eta, v), v_0, v_1, \dots, v_{n-1})$ has a locally asymptotically stable equilibrium at

the origin. To achieve semi-global stability one has to select L sufficient large and replace ψ with

$$\tilde{\psi}(\eta, v) = \begin{cases} \psi(\eta, v), & \text{if } \|\psi(\eta, v)\| < M, \\ M \frac{\psi(\eta, v)}{\|\psi(\eta, v)\|}, & \text{if } \|\psi(\eta, v)\| \geq M, \end{cases}$$

with $M > 0$ to be selected, as detailed in the following statement.

Theorem 3 Consider the system (10) with $m = p = 1$. Let $x_0 = 0$ be an achievable equilibrium. Assume $h(0) = 0$. Suppose the system is uniformly observable and there exists a smooth state feedback control law $u = \alpha(x)$ which globally asymptotically stabilizes the zero equilibrium and it is such that $\alpha(0) = 0$.

Then for each $R > 0$ there exist $\tilde{R} > 0$ and $M^* > 0$, and for each $M > M^*$ there exists L^* such that, for each $M > M^*$ and $L > L^*$ the dynamic output feedback control law

$$\begin{aligned} \dot{v}_0 &= v_1, \\ \dot{v}_1 &= v_2, \\ &\vdots \\ \dot{v}_{n-1} &= \tilde{\alpha}(\tilde{\psi}(\eta, v), v_0, v_1, \dots, v_{n-1}) \\ \dot{\eta}_0 &= \eta_1 + L c_{n-1}(y - \eta_0), \\ \dot{\eta}_1 &= \eta_2 + L^2 c_{n-2}(y - \eta_0), \\ &\vdots \\ \dot{\eta}_{n-1} &= \phi_n(\psi(\eta, v), v_0, v_1, \dots, v_{n-1}) \\ &\quad + L^n c_0(y - \eta_0), \\ u &= v_0, \end{aligned}$$

yields a closed-loop system with the following properties.

- The zero equilibrium of the system is locally asymptotically stable.
- For any $x(0)$, $v(0)$, and $\eta(0)$ such that $\|x(0)\| < R$ and $\|(v(0), \eta(0))\| < \tilde{R}$ the

trajectories of the closed-loop system are such that

$$\begin{aligned} \lim_{t \rightarrow \infty} x(t) &= 0, \\ \lim_{t \rightarrow \infty} v(t) &= 0, \\ \lim_{t \rightarrow \infty} \eta(t) &= 0. \end{aligned}$$

The foregoing result can be informally formulated as follows: global state feedback stabilizability and uniform observability imply semi-global stabilizability by output feedback. This can be regarded as a nonlinear enhancement of the so-called separation principle for the stabilization, by output feedback, of linear systems. Note, finally, that a global version of the separation principle can be derived under one additional assumption: the existence of an estimator of the norm of the state x .

Summary and Future Directions

A necessary condition and a sufficient condition for stabilizability of an equilibrium of a nonlinear system have been given, together with two systematic design methods. The necessary condition allows to rule out, using a simple algebraic test, existence of continuous stabilizers, whereas the sufficient condition provides a link with classical Lyapunov theory. In addition, the problem of semi-global stability by dynamic output feedback has been discussed in detail. Several issues have not been discussed, including the use of discontinuous, hybrid and time-varying feedbacks; stabilization by static output feedback and dynamic state feedback; and robust stabilization. Note finally that similar considerations can be carried out for nonlinear discrete-time systems.

Abstract

Mathematical finance is an important part of applied mathematics since the 1980s. At the beginning, the main goal was to price derivative products and to provide hedging strategies. Nowadays, the goal is to provide models for prices and interest rates, such that better calibration of parameters can be done. In these pages, we present some basic models. Details can be found in Musiela M, Rutkowski M (*Martingale methods in financial modelling*. Springer, Berlin, 2005).

Keywords

Affine process · Brownian process · Default times · Lévy process · Wishart distribution

Models for Prices of Stocks

The first model of prices was elaborated by Louis Bachelier, in his thesis (1900). The idea was that the dynamic of prices has a trend, perturbed by a noise. For this noise, Bachelier set the fundamental properties of the Brownian motion. Bachelier's prices were of the form

$$S_t^B = S_0^B + \nu t + \sigma W_t$$

where W is a Brownian motion.

This model, where prices can take negative values, was changed by taking the exponential as in the celebrated Black-Scholes-Merton model (BSM) where

$$S_t = e^{S_t^B} = S_0 \exp(vt + \sigma W_t).$$

Only two constant parameters were needed; the coefficient σ is called the volatility. From Itô's formula, the dynamics of the BSM's price are

$$dS_t = S_t(\mu dt + \sigma dW_t)$$

where $\mu = v + \frac{1}{2}\sigma^2$. The interest rate is assumed to be a constant r .

The price of a derivative product of payoff $H \in \mathcal{F}_T = \sigma(S_s, s \leq T)$ is obtained using a hedging procedure. One proves that there exists a (self-financing) portfolio with value V , investing in the savings account and in the stock S , with terminal value H , i.e., $V_T = H$. The price of H at time t is V_t . Using that methodology, the price of a European call with strike K (i.e., for $H = (S_T - K)^+$) is

$$V_t = BS(\sigma, K)_t := S_t \mathcal{N}(d_1) - K e^{-r(T-t)} \mathcal{N}(d_2)$$

where $\mathcal{N}$ is the cumulative distribution function of a standard Gaussian law and

$$d_1 = \frac{1}{\sigma \sqrt{T-t}} \left(\ln \left(\frac{S_t}{K e^{-r(T-t)}} \right) \right) + \frac{1}{2} \sigma \sqrt{T-t}, \quad d_2 = d_1 - \sigma \sqrt{T-t}$$

Note that the coefficient μ plays no role in this pricing methodology. This formula opened the door to the notion of risk neutral probability measure: the price of the option (or of any derivative product) is the expectation under the unique probability measure $\mathbb{Q}$, equivalent to $\mathbb{P}$ such that the discounted price $S_t e^{-rt}$, $t \geq 0$ is a $\mathbb{Q}$ martingale.

During one decade, the financial market was quite smooth, and this simple model was efficient to price derivative products and to calibrate the coefficients from the data. After the Black Monday of October 1987, the model was recognized

to suffer some weakness, and the door was fully open to more sophisticated models, with more parameters. In particular, the smile effect was seen on the data: the BSM formula being true, the price of the option would be a deterministic function of the fixed parameter σ and of K (the other parameter as maturity, underlying price, interest rate being fixed), and one would obtain, using $\psi(\cdot, K)$, the inverse of $BS(\cdot, K)$, the constant $\sigma = \psi(C^o(K), K)$, where $C^o(K)$ is the observed prices associated with the strike K . This is not the case, the curve $K \rightarrow \psi(C^o(K), K)$ having a smile shape (or a smirk shape). The BSM model is still used as a benchmark in the concept of implied volatility: for a given observed option price $C^o(K, T)$ (with strike K and maturity T), one can find the value of σ^* such that $BS(\sigma^*, K, T) = C^o(K, T)$. The surface $\sigma^*(K, T)$ is called the implied volatility surface and plays an important role in calibration issues.

Due to the need of more accurate formula, many models were presented, the only (mathematical) restriction being that prices have to be semi-martingales (to avoid arbitrage opportunities).

A first class is the stochastic volatility models. Assuming that the diffusion coefficient (called the local volatility) is a deterministic function of time and underlying, i.e.,

$$dS_t = S_t(\mu dt + \sigma(t, S_t) dW_t)$$

Dupire proved, using Kolmogorov backward equation, that the function σ is determined by the observed prices of call options by

$$\frac{1}{2} K^2 \sigma^2(T, K) \tag{1}$$

$$= \frac{\partial_T C^o(K, T) + r K \partial_K C^o(K, T)}{\partial_{KK}^2 C^o(K, T)} \tag{2}$$

where ∂_T (resp. ∂_K) is the partial derivative operator with respect to the maturity (resp., the strike). However, this important model (which allows hedging for derivative products) does not allow a full calibration of the volatility surface.

A second class consists of assuming that the volatility is a stochastic process. The first example is the Heston model which assumes that

$$\begin{aligned} dS_t &= S_t(\mu dt + \sqrt{v_t} dW_t) \\ dv_t &= -\lambda(v_t - \bar{v})dt + \eta\sqrt{v_t}dB_t \end{aligned}$$

where B and W are two Brownian motions with correlation factor ρ . This model is generalized by Gouriéroux and Sufana (2003) as Wishart model where the risky asset S is a d dimensional process, with matrix of quadratic variation Σ satisfy

$$\begin{aligned} dS_t &= \text{Diag}(S_t)(\mu dt + \sqrt{\Sigma_t} dW_t) \\ d\Sigma_t &= (\Lambda\Lambda^T + M\Sigma_t + \Sigma_t M^T)dt \\ &\quad + \sqrt{\Sigma_t} dB_t Q + Q^T (dB_t)^T \sqrt{\Sigma_t} \end{aligned}$$

where W is a d dimensional Brownian motion and B a $(d \times d)$ matrix Brownian; Λ , M , Q are $(d \times d)$ matrices; M is semidefinite negative; and $\Lambda\Lambda^T = \beta QQ^T$ with $\beta \geq d - 1$ to ensure strict positivity. The efficiency of these models was checked using calibration methodology; however, the main idea of hedging for pricing issues is forgotten: there is, in general, no hedging strategy, even for common derivative products, and the validation of the model (the form of the volatility, since the drift term plays no role in pricing) is done by calibration. The risk neutral probability is no more unique.

A new generation of stochastic volatility models where the instantaneous volatility is driven by a (rough) fractional Brownian motion is now studied (see Gatheral et al. 2018).

Interest Rate Models

In the beginning of the 1970s, a specific attention was paid for the interest rate modeling, a constant interest rate being far from the real world.

A first class consists of a dynamic for the instantaneous interest rate r .

Vasisek suggested an Ornstein-Uhlenbeck diffusion, i.e., $dr_t = a(b - r_t)dt + \sigma dW_t$, the solution being a Gaussian process of the form

$$r_t = (r_0 - b)e^{-at} + b + \sigma \int_0^t e^{-a(t-u)} dW_u.$$

This model is fully tractable; one of its weakness is that the interest rate can take negative values.

Cox, Ingersoll, and Rubinstein (CIR) studied the square root process

$$dr_t = a(b - r_t)dt + \sigma\sqrt{r_t}dB_t,$$

where $ab > 0$ (so that r is nonnegative). No closed form for r is known; however, closed form for the price of the associated zero coupons is known (see below in Affine Processes).

A second class is the celebrated Heath-Jarrow-Morton (HJM) model: the starting point being to model the price of a zero coupon with maturity T (i.e., an asset which pays one monetary unit at time T , these prices being observable) in terms of the instantaneous forward rate $f(t, T)$, as

$$B(t, T) = \exp\left(-\int_t^T f(t, u)du\right).$$

Assuming that

$$df(t, T) = \alpha(t, T)dt + \sigma(t, T)dW_t$$

one finds

$$dB(t, T) = B(t, T)(a(t, T)dt + b(t, T)dW_t)$$

where the relationship between a , b and α , β is known. The instantaneous interest rate is $r_t = f(t, t)$. This model is quite efficient; however, no conditions are known in order that the interest rate is positive.

The new generation of term structure models is devoted to modeling multiple yield curves which have emerged after the last financial crisis. In particular, an HJM approach to model the term structure of multiplicative spreads between FRA rates and simply compounded OIS risk-free

forward rates is provided in Grbac and Runggaldier (2016).

Models with Jumps

Lévy Processes

Following the idea to produce tractable models to fit the data, many models are now based on Lévy's processes. These models are used for modeling prices as $S_t = e^{X_t}$ where X is a Lévy process. They present a nice feature: even if closed forms for pricing are not known, numerical methods are efficient. One of the most popular is the Carr-Geman-Madan-Yor (CGMY) model which is a Lévy process without Gaussian component and with Lévy density

$$\frac{C}{x^{Y+1}} e^{-Mx} \mathbb{1}_{\{x>0\}} + \frac{C}{|x|^{Y+1}} e^{Gx} \mathbb{1}_{\{x<0\}}$$

with $C > 0$, $M \geq 0$, $G \geq 0$, and $Y < 2$.

These models are often presented as a special case of a change of time: roughly speaking, any semi-martingale is a time-changed Brownian motion, and many examples are constructed as $S_t = B_{A_t}$, where B is a Brownian motion and A an increasing process (the change of time), chosen independent of B (for simplicity) and A a Lévy process (for computational issues).

Affine Processes

Affine models were introduced by Duffie et al. (2003) and are now a standard tool for modeling stock prices or interest rates. An affine process enjoys the property that, for any affine function g ,

$$\begin{aligned} \mathbb{E}(\exp(uX_T + \int_t^T g(X_s)ds) | \mathcal{F}_t) \\ = \exp(\alpha(t, T)X_t + \beta(t, T)) \end{aligned}$$

where α and β are deterministic solutions of PDEs.

A class of affine processes X ($\mathbb{R}^n$ -valued) is the one where

$$dX_t = b(X_t)dt + \sigma(X_t)dW_t + dZ_t$$

where the drift vector b is an affine function of x , the covariance matrix $\sigma(x)\sigma^T(x)$ is an affine function of x , W is an n -dimensional Brownian motion, and Z is a pure jump process whose jumps have a given law ν on $\mathbb{R}^n$ and arrive with intensity $f(X_t)$ where f is an affine function. An example is the CIR model (without jumps), where one can find the price of a zero coupon as

$$\begin{aligned} \mathbb{E}(\exp(-\int_t^T r_s ds) | \mathcal{F}_t) \\ = \Phi(T-t) \exp[-r_t \Psi(T-t)] \end{aligned}$$

where

$$\begin{aligned} \Psi(s) &= \frac{2(e^{\gamma s} - 1)}{(\gamma + a)(e^{\gamma s} - 1) + 2\gamma}, \\ \Phi(s) &= \left(\frac{2\gamma e^{(\gamma+a)\frac{s}{2}}}{(\gamma + a)(e^{\gamma s} - 1) + 2\gamma} \right)^{\frac{2ab}{\sigma^2}}, \\ \gamma^2 &= a^2 + 2\sigma^2. \end{aligned}$$

Models for Defaults

At the end of the 1990s, new kinds of financial products appear on the market: defaultable options, defaultable zero coupons, and credit derivatives, as the CDOs. Then, particular attention was paid to the modeling of default times; see Bielecki and Rutkowski (2001). The most popular model for a single default is the reduced form approach, which is based on the knowledge of the intensity rate process. Given a nonnegative process λ , adapted with respect to a reference filtration $\mathbb{F}$, a random time τ is defined so that

$$\mathbb{P}(\tau > t | \mathcal{F}_\infty) = \exp(-\int_0^t \lambda_s ds)$$

This implies that $\mathbb{1}_{\tau \leq t} - \int_0^{t \wedge \tau} \lambda_u du$ is a martingale (in the smallest filtration $\mathbb{G}$ which contains $\mathbb{F}$

and makes τ a random time). This intensity rate λ plays the role of the interest spread due to the equality, for any $Y \in \mathcal{F}_T$ and $\mathbb{F}$ adapted interest rate r

$$\begin{aligned} \mathbb{E}(Y \mathbb{1}_{T < \tau} \exp(-\int_t^T r_s ds) | \mathcal{G}_t) \mathbb{1}_{t < \tau} \\ = \mathbb{1}_{t < \tau} \mathbb{E}(Y \exp(-\int_t^T (r_s + \lambda_s) ds) | \mathcal{F}_t) \end{aligned}$$

The real challenge is to model multi-defaults. Defaults are assumed to occur at times τ_i , and one has to describe the (conditional) joint law of the vector $\tau = (\tau_1, \tau_2, \dots, \tau_n)$, the number n of defaults being quite large (100). A first step is to study the law of the defaults, i.e.,

$$\mathbb{P}(\tau_1 > t_1, \dots, \tau_n > t_n)$$

which is performed using the classical copula approach, based on the knowledge of the marginal laws of the τ_i , i.e., on the knowledge of $\mathbb{P}(\tau_i \leq s) =: F_i(s)$ where the cumulative distribution functions F_i are assumed invertible. The simplest and most popular copula being the Gaussian one

$$\begin{aligned} \mathbb{P}(F_i^{-1}(\tau_i) \leq u_i, i = 1, \dots, n) \\ = \mathcal{N}_{\Sigma}^n \left(\mathcal{N}^{-1}(u_1), \dots, \mathcal{N}^{-1}(u_n) \right), \end{aligned}$$

where $\mathcal{N}_{\Sigma}^n$ is the c.d.f. for the n -variate central normal distribution with the linear correlation matrix Σ and $\mathcal{N}^{-1}$ is the inverse of the c.d.f. for the univariate standard normal distribution. However, a dynamical model was needed, mainly to study the contagion effect, i.e., how the occurrence of a default affect the probability of occurrence of the next defaults.

A first class of models is based on the intensity: starting from a given family of intensities $(\lambda_t^i, i = 1, \dots, n)$ which satisfies

$$d\lambda_t^i = f(t, \lambda_t^i)dt + g(t, \lambda_t^i)dW_t + dL_t^{(-i)}$$

where $L_t^{(-i)} = \sum_{k \neq i} \beta_k \mathbb{1}_{\tau_k \leq t}$, one constructs random times having the given intensities.

Another class of models, which allows for common jumps, is based on Markov Chains with absorbing state, the default time of the i -th entity being the time where the i -th component of the Markov Chain enters in the absorbing state. These models are efficient due to the introduction of common factors.

Many studies are done to find a form of a dynamic copula, i.e., a family of processes $G_t(\theta), t \geq 0$ such that

$$G_t(\theta) = \mathbb{P}(\tau_1 > \theta_1, \dots, \tau_n > \theta_n | \mathcal{F}_t)$$

Some examples where, for any fixed t , the quantity $G_t(\cdot)$ is a (stochastic) Gaussian law are known; however, there are few concrete examples for other cases.

Abstract

The linear-quadratic (LQ) problem is the prototype of a large number of optimal control problems, including the fixed endpoint, the point-to-point, and several H_2/H_∞ control problems, as well as the dual counterparts. In the past 50 years, these problems have been addressed using different techniques, each tailored to their specific structure. It is only in the last 10 years that it was recognized that a unifying framework is available. This framework hinges on formulae that parameterize the solutions of the Hamiltonian differential equation in the continuous-time case and the solutions of the extended symplectic system in the discrete-time case. Whereas traditional techniques involve the solutions of Riccati differential or difference equations, the formulae used here to solve the finite-horizon LQ control problem only rely on solutions of the algebraic Riccati equations. In this entry, aspects of the framework are described within a discrete-time context.

Keywords

Cyclic boundary conditions · Discrete-time linear systems · Fixed end-point · Initial value · Point-to-point boundary conditions · Quadratic cost · Riccati equations

Introduction

Ever since the *linear-quadratic* (LQ) optimal control problem was introduced in the 1960s by Kalman in his pioneering paper (1960), it has found countless applications in areas such as chemical process control, aeronautics, robotics, servomechanisms, and motor control, to name but a few.

For details on the *raisons d'être* of LQ problems, readers are referred to the classical textbooks on this topic (Kwakernaak and Sivan 1972; Anderson and Moore 1971) and to the Special Issue on LQ optimal control problems in *IEEE Trans. Aut. Contr.*, vol. AC-16, no. 6, 1971. The LQ regulator is not only important per se. It is also the prototype of a variety of fundamental optimization problems. Indeed, several optimal control problems that are extremely relevant in practice can be recast into composite LQ, dual LQ, or generalized LQ problems. Examples include LQG, H_2 and H_∞ problems, and Kalman filtering problems. Moreover, LQ optimal control is intimately related, via matrix Riccati equations, to absolute stability, dissipative networks, and optimal filtering. The importance of LQ problems is not restricted to linear systems. For example, LQ control techniques can be used to modify an optimal control law in response to perturbations in the dynamics of a nonlinear plant. For these reasons, the LQ problem is universally regarded as a cornerstone of modern control theory.

In its simplest and most classical version, the finite-horizon discrete LQ optimal control can be stated as follows:

Problem 1 Let $A \in \mathbb{R}^{n \times n}$ and $B \in \mathbb{R}^{n \times m}$, and consider the linear system

$$x_{t+1} = Ax_t + Bu_t, \quad y_t = Cx_t + Du_t, \quad (1)$$

where the initial state $x_0 \in \mathbb{R}^n$ is given. Let $W = W^\top \in \mathbb{R}^{n \times n}$ be positive semidefinite. Find a sequence of inputs u_t , with $t = 0, 1, \dots, N-1$, minimizing the cost function

$$J_{N,x_0}(u) \stackrel{\text{def}}{=} \sum_{t=0}^{N-1} \|y_t\|^2 + x_N^\top W x_N. \quad (2)$$

Historically, LQ problems were first introduced and solved by Kalman in (1960). In this paper, Kalman showed that the LQ problem can be solved for *any* initial state x_0 , and the optimal control can be written as a state feedback $u(t) = K(t)x(t)$, where $K(t)$ can be found by solving a famous quadratic matrix difference equation known as the *Riccati equation*. When W is no longer assumed to be positive semidefinite, the optimal solution may or may not exist. A complete analysis of this case has been worked out in Bilardi and Ferrante (2007). In the infinite-horizon case (i.e., when N is infinite), the optimal control (when it exists) is stationary and may be computed by solving an *algebraic* Riccati equation (Kwakernaak and Sivan 1972; Anderson and Moore 1971).

Since its introduction, the original formulation of the classic LQ optimal control problem has been generalized in several different directions, to accommodate for the need of considering more general scenarios than the one represented by Problem 1. Examples include the so-called fixed endpoint LQ, in which the extreme states are sharply assigned, and the *point-to-point* case, in which the initial and terminal values of an output of the system are constrained to be equal to specified values. This led to a number of contributions in the area where different adaptations of the Riccati theory were tailored to these diversified contexts of LQ optimal control. These variations of the classic LQ problem are becoming increasingly important due to their use in several applications of interest. Indeed, many applications including spacecraft, aircraft, and chemical processes involve maneuvering between two states during some phases of a typical mission. Another interesting example is the H_2 -optimization of transients in switching plants, where the problem can be divided into a set of finite-horizon LQ problems with

welding conditions on the optimal arcs for each switch instant. This problem has been the object of a large number of contributions in the recent literature, under different names: Parameter varying systems, jump linear systems, switching systems, and bumpless systems are definitions extensively used to denote different classes of systems affected by sensible changes in their parameters or structures (Balas and Bokor 2004). In recent years, a new unified approach emerged in Ferrante et al. (2005), Ferrante and Ntogramatzidis (2005, 2007a, b) that solves the finite-horizon LQ optimal control problem via a formula which parameterizes the set of trajectories generated by the corresponding Hamiltonian differential equation in the continuous time and the extended symplectic difference equation in the discrete case. Loosely, we can say that the expressions parameterizing the trajectories of the Hamiltonian differential equation and the extended symplectic difference equation using this approach hinge on a pair of “opposite” solutions of the associated algebraic Riccati equations. This active stream of research considerably enlarged the range of optimal control problems that can be successfully addressed. This point of view always requires some controllability-type assumption and the extended symplectic pencil (Ferrante and Ntogramatzidis 2005, 2007b) to be regular and devoid of generalized eigenvalues on the unit circle. More recently, a new point of view has emerged which yields a more direct solution to this problem, without requiring system-theoretic assumptions (Ntogramatzidis and Ferrante 2013; Ferrante and Ntogramatzidis 2013a, b).

The discussion here is restricted to the discrete-time case; for the corresponding continuous-time counterpart, we will only make some comments and refer to the literature.

Notation For the reader’s convenience, we briefly review some, mostly standard, matrix notation used throughout the paper. Given a matrix $B \in \mathbb{R}^{n \times m}$, we denote by $B^\top$ its *transpose*

and by $B^\dagger$ its *Moore-Penrose pseudo-inverse*, the unique matrix $B^\dagger$ that satisfies $BB^\dagger B = B$, $B^\dagger BB^\dagger = B^\dagger$, $(BB^\dagger)^\top = BB^\dagger$, and $(B^\dagger B)^\top = B^\dagger B$. The *kernel* of B is the subspace $\{x \in \mathbb{R}^n \mid Bx = 0\}$ and is denoted $\ker B$. The *image* of B is the subspace $\{y \in \mathbb{R}^m \mid \exists x \in \mathbb{R}^n : y = Ax\}$ and is denoted by $\text{im } B$. Given a square matrix A , we denote by $\sigma(A)$ its *spectrum*, i.e., the set of its eigenvalues. We write $A_1 > A_2$ (resp. $A_1 \geq A_2$) when $A_1 - A_2$ is *positive definite* (resp. *positive semidefinite*).

Classical Finite-Horizon Linear-Quadratic Optimal Control

The simplest classical version of the finite-horizon LQ optimal control is Problem 1. By employing some standard linear algebra, this problem may be solved by the classical technique known as “completion of squares”: First of all, the cost can be rewritten as

$$J_{N,x_0}(u) = \sum_{t=0}^{N-1} [x_t^\top \ u_t^\top] \begin{bmatrix} Q + A^\top X_{t+1} A - X_t & S + A^\top X_{t+1} B \\ S^\top + B^\top X_{t+1} A & R + B^\top X_{t+1} B \end{bmatrix} \begin{bmatrix} x_t \\ u_t \end{bmatrix} + x_N^\top (W - X_N) x_N + x_0^\top X_0 x_0, \quad (6)$$

which holds for any sequence of matrices X_t . With $X_N \stackrel{\text{def}}{=} W$ fixed, for $t = N-1, N-2, \dots, 0$, let

$$X_t \stackrel{\text{def}}{=} Q + A^\top X_{t+1} A - (S + A^\top X_{t+1} B) (R + B^\top X_{t+1} B)^\dagger (S^\top + B^\top X_{t+1} A). \quad (7)$$

It is now easy to see that all the matrices of the sequence X_t defined above are positive semidefinite. Indeed, $X_N = W \geq 0$. Assume by induction that $X_{t+1} \geq 0$. Then,

$$M_{t+1} \stackrel{\text{def}}{=} \begin{bmatrix} Q + A^\top X_{t+1} A & S + A^\top X_{t+1} B \\ S^\top + B^\top X_{t+1} A & R + B^\top X_{t+1} B \end{bmatrix} = \Pi + \begin{bmatrix} A^\top \\ B^\top \end{bmatrix} X_{t+1} \begin{bmatrix} A & B \end{bmatrix} \geq 0.$$

$$J_{N,x_0}(u) = \sum_{t=0}^{N-1} [x_t^\top \ u_t^\top] \Pi \begin{bmatrix} x_t \\ u_t \end{bmatrix} + x_N^\top W x_N, \quad (3)$$

with

$$\Pi \stackrel{\text{def}}{=} \begin{bmatrix} Q & S \\ S^\top & R \end{bmatrix} \stackrel{\text{def}}{=} \begin{bmatrix} C^\top \\ D^\top \end{bmatrix} [C \ D] = \Pi^\top \geq 0. \quad (4)$$

Now, let $X_0, X_1, \dots, X_N$ be an arbitrary sequence of $n \times n$ symmetric matrices. We have the identity

$$\left(\sum_{t=0}^{N-1} [x_{t+1}^\top X_{t+1} x_{t+1} - x_t^\top X_t x_t] \right) + x_0^\top X_0 x_0 - x_N^\top X_N x_N = 0. \quad (5)$$

Adding (5)–(3) and using the expression (1) for x_{t+1} , we get

Since X_t is the generalized Schur complement of the right upper block of M_{t+1} in M_{t+1} , it follows that $X_t \geq 0$, which in turns implies

$$R + B^\top X_t B \geq 0.$$

Moreover, by employing Eq.(7) and recalling that, given a positive semidefinite matrix $\Pi_0 = \begin{bmatrix} Q_0 & S_0 \\ S_0^\top & R_0 \end{bmatrix} = \Pi_0^\top \geq 0$, we have $\begin{bmatrix} S_0 & R_0^\dagger S_0^\top & S_0 \\ & S_0^\top & R_0 \end{bmatrix} = \begin{bmatrix} S_0 \\ R_0 \end{bmatrix} R_0^\dagger \begin{bmatrix} S_0^\top & R_0 \end{bmatrix} \geq 0$, we easily see that

$$M_{t+1} - \begin{bmatrix} X_t & 0 \\ 0 & 0 \end{bmatrix} = \begin{bmatrix} S + A^\top X_{t+1} B \\ R + B^\top X_{t+1} B \end{bmatrix} (R + B^\top X_t B)^\dagger \begin{bmatrix} S^\top + A^\top X_{t+1} B & R + B^\top X_{t+1} B \end{bmatrix} \geq 0.$$

Hence, (6) takes the form

$$J_{N,x_0}(u) = \sum_{t=0}^{N-1} \left\| [(R + B^\top X_{t+1} B)^\dagger]^{1/2} \right. \\ \times [(S^\top + B^\top X_{t+1} A)x_t \\ \left. + (R + B^\top X_{t+1} B)u_t \right\|_2^2 \\ + x_0^\top X_0 x_0. \quad (8)$$

Now it is clear that u_t is optimal if and only if

$$[(R + B^\top X_{t+1} B)^\dagger]^{1/2} [(S^\top + B^\top X_{t+1} A)x_t \\ + (R + B^\top X_{t+1} B)u_t] = 0,$$

whose solutions are parameterized by the feedback control

$$u_t = -K_t x_t + G_t v_t, \quad (9)$$

where $K_t \stackrel{\text{def}}{=} (R + B^\top X_{t+1} B)^\dagger (S^\top + B^\top X_{t+1} A)$ and $G_t \stackrel{\text{def}}{=} [I - (R + B^\top X_{t+1} B)^\dagger (R + B^\top X_{t+1} B)]$ is the orthogonal projector onto the linear space of vectors that can be added to the optimal control u_t without affecting optimality and v_t is a free parameter. The optimal state trajectory is now given by the closed-loop dynamics

$$x_{t+1} = (A - B K_t)x_t + B G_t v_t. \quad (10)$$

The optimal cost is clearly

$$J^* = x_0^\top X_0 x_0. \quad (11)$$

The corresponding results in continuous time can be obtained along the same lines as the discrete-time case; see Ferrante and Ntogramatzidis (2013b) and references therein.

More General Linear-Quadratic Problems

The problem discussed in the previous section presents some limitations that prevent its applicability in several important situations. In

particular, three relevant generalizations of the classical problem are:

1. *The fixed endpoint case*, where the states at the endpoints x_0 and x_N are both assigned.
2. *The point-to-point case*, where the initial and terminal values z_0 and z_N of linear combination $z_t = V x_t$ of the state of the dynamical system described by (1) are constrained to be equal to two assigned vectors.
3. *The cyclic case*, where the states at the endpoints x_0 and x_N are not sharply assigned, but they are constrained to be equal (clearly, we can have combinations of (2) and (3)).

All these problems are special cases of a general LQ problem that can be stated as follows:

Problem 2 Consider the dynamical setting (1) of Problem 1. Find a sequence of inputs u_t , with $t = 0, 1, \dots, N-1$ and an initial state x_0 minimizing the cost function

$$J_{N,x_0}(u) \stackrel{\text{def}}{=} \sum_{t=0}^{N-1} \|y_t\|^2 + [x_0^\top - \bar{x}_0^\top \quad x_N^\top - \bar{x}_N^\top] \\ \times \begin{bmatrix} W_{11} & W_{12} \\ W_{12}^\top & W_{22} \end{bmatrix} \begin{bmatrix} x_0 - \bar{x}_0 \\ x_N - \bar{x}_N \end{bmatrix} \quad (12)$$

under the dynamic constraints (1) and the endpoints constraints

$$V \begin{bmatrix} x_0 \\ x_N \end{bmatrix} = v. \quad (13)$$

Here $W \stackrel{\text{def}}{=} \begin{bmatrix} W_{11} & W_{12} \\ W_{12}^\top & W_{22} \end{bmatrix}$ is a positive semidefinite matrix (partitioned in four blocks) that quadratically penalizes the differences between the initial state x_0 and a desired initial state $\bar{x}_0$ and between the final state x_N and a desired final state $\bar{x}_N$ (this general problem formulation can also encompass problems where the difference $x_0 - x_N$ is not fixed but has to be quadratically penalized with a matrix $\Delta = \Delta^\top \geq 0$ in the performance index $J'_{N,x_0}(u) = \sum_{t=0}^{N-1} [x_t^\top \quad u_t^\top] \Pi \begin{bmatrix} x_t \\ u_t \end{bmatrix} + (x_0 - x_N)^\top \Delta (x_0 - x_N)$). It is simple to see that this

performance index can be brought back to (12) by setting $W = \begin{bmatrix} \Delta & -\Delta \\ -\Delta & \Delta \end{bmatrix}$ and $\bar{x}_0 = \bar{x}_N = 0$. Equation (13) permits to impose also a hard constraint on an arbitrary linear combination of initial and final states.

The solution of Problem 2 can be obtained by parameterizing the solutions of the so-called extended symplectic system (see Ferrante and Levy (1998) and references therein for a discussion on symplectic matrices and pencils). This solution can be convenient also for the classical case of Problem 1. In fact it does not require to iterate the difference Riccati equation (which can be undesirable if the time horizon is large) but only to solve an algebraic Riccati equation and a related discrete Lyapunov equation.

This solution requires some definitions, preliminary results, and standing assumptions (see Ntogramatzidis and Ferrante (2013) and Ferrante and Ntogramatzidis (2013a) for a more general approach which does not require such assumptions). A detailed proof of the main result can be found in Ferrante and Ntogramatzidis (2007b); see also Zattoni (2008) and Ferrante and Ntogramatzidis (2012). The extended symplectic pencil is defined by

$$\begin{aligned} zF - G, \quad F &\stackrel{\text{def}}{=} \begin{bmatrix} I_n & 0 & 0 \\ 0 & -A^\top & 0 \\ 0 & -B^\top & 0 \end{bmatrix}, \\ G &\stackrel{\text{def}}{=} \begin{bmatrix} A & 0 & B \\ Q & -I_n & S \\ S^\top & 0 & R \end{bmatrix}, \end{aligned} \quad (14)$$

where Q, S, R are defined as in (3). We make the following assumptions:

- (A1) The pair (A, B) is *modulus controllable*, i.e., $\forall \lambda \in \mathbb{C} \setminus \{0\}$ at least one of the two matrices $[\lambda I - A \mid B]$ and $[\lambda^{-1} I - A \mid B]$ has full row rank.
- (A2) The pencil $zF - G$ is regular (i.e., $\det(zF - G)$ is not the zero polynomial) and has no generalized eigenvalues on the unit circle.

Consider the discrete algebraic Riccati equation

$$\begin{aligned} X &= A^\top X A - (A^\top X B + S)(R + B^\top X B)^{-1} \\ &\quad (S^\top + B^\top X A) + Q. \end{aligned} \quad (15)$$

Under assumptions (A1)–(A2), (15) admits a strongly unmixed solution $X = X^\top$, i.e., a solution X for which the corresponding closed-loop matrix

$$\begin{aligned} A_X &\stackrel{\text{def}}{=} A - B K_X, \quad \text{with} \\ K_X &\stackrel{\text{def}}{=} (R + B^\top X B)^{-1}(S^\top + B^\top X A), \end{aligned} \quad (16)$$

has spectrum that does not contain reciprocal values, i.e., $\lambda \in \sigma(A_X)$ implies $\lambda^{-1} \notin \sigma(A_X)$. It can now be proven that the following closed-loop Lyapunov equation admits a unique solution $Y = Y^\top \in \mathbb{R}^{n \times n}$:

$$A_X Y A_X^\top - Y + B(R + B^\top X B)^{-1} B^\top = 0. \quad (17)$$

The following theorem provides an explicit formula parameterizing all the optimal state and control trajectories for Problem 2. Notice that this formula can be readily implemented starting from the problem data.

Theorem 1 *With reference to Problem 2, assume that (A1) and (A2) are satisfied. Let $X = X^\top$ be any strongly unmixed solution of (15) and $Y = Y^\top$ be the corresponding solution of (17). Let N_V be a basis matrix (in the case when $\ker V = \{0\}$, we consider N_V to be void) of the null space of V . Moreover, let*

$$\begin{aligned} F &\stackrel{\text{def}}{=} A_X^N, \\ K_\star &\stackrel{\text{def}}{=} K_X Y A_X^\top - (R + B^\top X B)^{-1} B^\top, \\ \hat{X} &\stackrel{\text{def}}{=} \text{diag}(-X, X), \quad \bar{x} \stackrel{\text{def}}{=} \begin{bmatrix} \bar{x}_0 \\ \bar{x}_N \end{bmatrix}, \\ w &\stackrel{\text{def}}{=} \begin{bmatrix} v \\ -N_V^\top W \bar{x} \end{bmatrix}, \quad L \stackrel{\text{def}}{=} \begin{bmatrix} I_n & Y F^\top \\ F & Y \end{bmatrix}, \\ U &\stackrel{\text{def}}{=} \begin{bmatrix} 0 & -F^\top \\ 0 & I_n \end{bmatrix}, \end{aligned}$$

$$M \stackrel{\text{def}}{=} \begin{bmatrix} V L \\ N_V^\top [(\hat{X} - W) L - U] \end{bmatrix}.$$

$$\mathcal{P} \stackrel{\text{def}}{=} \{\pi = M^\dagger w + N_M \zeta \mid \zeta \text{ arbitrary}\}. \quad (18)$$

Problem 2 admits solutions if and only if $w \in \text{im } M$. In this case, let N_M be a basis matrix of the null space of M , and define

Then, the set of optimal state and control trajectories of Problem 2 is parameterized in terms of $\pi \in \mathcal{P}$, by

$$\begin{bmatrix} x(t) \\ u(t) \end{bmatrix} = \begin{cases} \begin{bmatrix} A_X^t & Y (A_X^\top)^{N-t} \\ -K_X A_X^t & -K_\star (A_X^\top)^{N-t-1} \end{bmatrix} \pi, & 0 \leq t \leq N-1, \\ \begin{bmatrix} A_X^N & Y \\ 0 & 0 \end{bmatrix} \pi, & t = N. \end{cases} \quad (19)$$

F

The interpretation of the above result is the following. As π varies, (19) describes the trajectories of the extended symplectic system. The set $\mathcal{P}$ defined in (18) is the set of π for which these trajectories satisfy the boundary conditions. All the details of this construction can be found in Ferrante and Ntogramatzidis (2007b). If the pair (A, B) is stabilizable, we can choose $X = X^\top$ to be the stabilizing solution of (15). In such case, the matrices A_X^t , $(A_X^\top)^{N-t}$ and $(A_X^\top)^{N-t-1}$ appearing in (19) are asymptotically stable for all $t = 0, \dots, N$. Thus, in this case, the optimal state trajectory and control are expressed in terms of powers of strictly stable matrices in the overall time interval, thus ensuring the robustness of the obtained solution even for very large time horizons. Indeed, the stabilizing solution of an algebraic Riccati equation and the solution of a Lyapunov equation may be computed by standard and robust algorithms available in any control package (see the MATLAB[®] routines `dare.m` and `dlyap.m`). We refer to Ferrante et al. (2005) and Ferrante and Ntogramatzidis (2013b) for the continuous-time counterpart of the above results.

Summary

With the technique discussed in this entry, a large number of LQ problems can be tackled in a unified framework. Moreover, several finite-horizon LQ problems that can be interesting and

useful in practice can be recovered as particular cases of the control problem considered here. The generality of the optimal control problem herein considered is crucial in the solution of several $H_2 - H_\infty$ optimization problems whose optimal trajectory is composed of a set of arches, each one solving a parametric LQ subproblem in a specific time horizon and all joined together at the end-points of each subinterval. In these cases, in fact, a very general form of constraint on the extreme states is essential in order to express the condition of conjunction of each pair of subsequent arches at the endpoints.

Flexible Robots

Alessandro De Luca

Sapienza Università di Roma, Roma, Italy

Abstract

Mechanical flexibility in robot manipulators is due to compliance at the joints and/or distributed deflection of the links. Dynamic models of the two classes of robots with flexible joints or flexible links are presented, together with control laws addressing the motion tasks of regulation to constant equilibrium states and of asymptotic tracking of output trajectories. Control design for robots with flexible joints takes advantage of the passivity and feedback linearization properties. In robots with flexible links, basic differences arise when controlling the motion at the joint level or at the tip level.

Keywords

Feedback linearization · Gravity compensation · Joint elasticity · Link flexibility · Noncausal and stable inversion · Regulation by motor feedback · Singular perturbation · Vibration damping

Introduction

Robot manipulators are usually considered as rigid multi-body mechanical systems. This ideal assumption simplifies dynamic analysis and control design but may lead to performance degradation and even unstable behavior, due to the excitation of vibrational phenomena.

Flexibility is mainly due to the limited stiffness of transmissions at the joints (Sweet and Good 1985) and to the deflection of slender and lightweight links (Cannon and Schmitz 1984). Joint flexibility is common when motion transmission/reduction elements such as belts, long shafts, cables, harmonic drives, or cycloidal gears

are used. Link flexibility is present in large articulated structures, such as very long arms needed for accessing hostile environments (deep sea or space) or automated crane devices for building construction. In both situations, static displacements and dynamic oscillations are introduced between the driving actuators and the actual position of the robot end effector. Undesired vibrations are typically confined beyond the closed-loop control bandwidth, but flexibility cannot be neglected when large speed/acceleration and high accuracy are requested by the task.

In the dynamic modeling, flexibility is assumed concentrated at the robot joints or distributed along the robot links (most of the times with some finite-dimensional approximation). In both cases, additional generalized coordinates are introduced beside those used to describe the rigid motion of the arm in a Lagrangian formulation. As a result, the number of available control inputs is strictly less than the number of degrees of freedom of the mechanical system. This type of under-actuation, though counterbalanced by the presence of additional potential energy helping to achieve system controllability, suggests that the design of satisfactory motion control laws is harder than in the rigid case.

From a control point of view, different design approaches are needed because of structural differences arising between flexible-joint and flexible-link robots. These differences hold for single- or multiple-link robots, in the linear or nonlinear domain, and depend on the physical co-location or not of mechanical flexibility versus control actuation, as well as on the choice of controlled outputs.

In order to measure the state of flexible robots for trajectory tracking control or feedback stabilization purposes, a large variety of sensing devices can be used, including encoders, joint torque sensors, strain gauges, accelerometers, and high-speed cameras. In particular, measuring the full state of the system would require twice the number of sensors than in the rigid case for robots with flexible joints and possibly more for robots with flexible links. The design of

controllers that work provably good with a reduced set of measurements is thus particularly attractive.

Robots with Flexible Joints

Dynamic Modeling

A robot with flexible joints is modeled as an open kinematic chain of $n + 1$ rigid bodies, interconnected by n joints undergoing deflection, and actuated by n electrical motors. Let θ be the n -vector of motor (i.e., rotor) positions, as reflected through the reduction gears, and q the n -vector of link positions. The joint deflection is $\delta = \theta - q \neq 0$. The standard assumptions are:

- A1** Joint deflections δ are small, limited to the domain of linear elasticity. The elastic torques due to joint deformations are $\tau_J = K(\theta - q)$, where K is the positive definite, diagonal joint stiffness matrix.
- A2** The rotors of the electrical motors are modeled as uniform bodies having their center of mass on the rotation axis.
- A3** The angular velocity of the rotors is due only to their own spinning.

The last assumption, introduced by Spong (1987), is very reasonable for large reduction ratios and also crucial for simplifying the dynamic model.

From the gravity and elastic potential energy, $\mathcal{U} = \mathcal{U}_g + \mathcal{U}_\delta$, and the kinetic energy $\mathcal{T}$ of the robot, applying the Euler-Lagrange equations to the Lagrangian $\mathcal{L} = \mathcal{T} - \mathcal{U}$ and neglecting all dissipative effects leads to the dynamic model

$$M(q)\ddot{q} + n(q, \dot{q}) + K(q - \theta) = 0 \quad (1)$$

$$B\ddot{\theta} + K(\theta - q) = \tau, \quad (2)$$

where $M(q)$ is the positive definite, symmetric inertia matrix of the robot links (including the motor masses); $n(q, \dot{q})$ is the sum of Coriolis and centrifugal terms $c(q, \dot{q})$ (quadratic in $\dot{q}$) and gravitational terms $g(q) = (\partial \mathcal{U}_g / \partial q)^T$; B is

the positive definite, diagonal matrix of motor inertias (reflected through the gear ratios); and τ are the motor torques (performing work on θ). The inertia matrix of the *complete* system is then $\mathcal{M}(q) = \text{block diag}\{M(q), B\}$. The two n -dimensional second-order differential equations (1) and (2) are referred to as the *link* and the *motor* equations, respectively. When the joint stiffness $K \rightarrow \infty$, it is $\theta \rightarrow q$ and $\tau_J \rightarrow \tau$, so that the two equations collapse in the limit into the standard dynamic model of rigid robots with total inertia $\mathcal{M}(q) = M(q) + B$. On the other hand, when the joint stiffness K is relatively large but still finite, robots with elastic joints show a *two-time-scale* dynamic behavior. A common large scalar factor $1/\epsilon^2 \gg 1$ can be extracted from the diagonal stiffness matrix as $K = \hat{K}/\epsilon^2$. The *slow* subsystem is associated to the link dynamics

$$M(q)\ddot{q} + n(q, \dot{q}) = \tau_J, \quad (3)$$

while the *fast* subsystem takes the form

$$\epsilon^2 \ddot{\tau}_J = \hat{K} \left(B^{-1} (\tau - \tau_J) + M^{-1}(q) (n(q, \dot{q}) - \tau_J) \right) \quad (4)$$

For small ϵ , Eqs. (3) and (4) represent a singularly perturbed system. The two separate time scales governing the slow and fast dynamics are t and $\sigma = t/\epsilon$.

Regulation

The basic robotic task of moving between two arbitrary equilibrium configurations is realized by a feedback control law that asymptotically stabilizes the desired robot state.

In the absence of gravity ($g \equiv 0$), the equilibrium states are parameterized by the desired reference position q_d of the links and take the form $q = q_d$, $\theta = \theta_d = q_d$ (with no joint deflection at steady state) and $\dot{q} = \dot{\theta} = 0$. As a result of passivity of the mapping from τ to $\dot{\theta}$, global regulation is achieved by a *decentralized PD* law using only feedback from the motor variables,

$$\tau = K_P(\theta_d - \theta) - K_D\dot{\theta}, \quad (5)$$

with diagonal $K_P > 0$ and $K_D > 0$.

In the presence of gravity, the (unique) equilibrium position of the motor associated with a desired link position q_d becomes $\theta_d = q_d + K^{-1}g(q_d)$. Global regulation is obtained by adding an extra gravity-dependent term τ_g to the PD control law (5),

$$\tau = K_P(\theta_d - \theta) - K_D\dot{\theta} + \tau_g, \quad (6)$$

with diagonal matrices $K_P > 0$ (at least) and $K_D > 0$. The term τ_g needs to match the gravity load $g(q_d)$ at steady state. The following choices are of slight increasing control complexity, with progressively better transient performance.

- *Constant* gravity compensation: $\tau_g = g(q_d)$. Global regulation is achieved when the smallest positive gain in the diagonal matrix K_P is large enough (Tomei 1991). This sufficient condition can be enforced only if the joint stiffness K dominates the gradient of gravity terms.
- *Online* gravity compensation: $\tau_g = g(\tilde{\theta})$, $\tilde{\theta} = \theta - K^{-1}g(q_d)$. Gravity effects on the links are approximately compensated during robot motion. Global regulation is proven under the same conditions above (De Luca et al. 2005).
- *Quasi-static* gravity compensation: $\tau_g = g(\tilde{q}(\theta))$. At any measured motor position θ , the link position $\tilde{q}(\theta)$ is computed by solving numerically $g(q) + K(q - \theta) = 0$. This removes the need of a strictly positive lower bound on K_P (Kugi et al. 2008), but the joint stiffness should still dominate the gradient of gravity terms.
- *Exact* gravity cancelation: $\tau_g = g(q) + BK^{-1}\dot{g}(q)$. This law requires full-state measurements (through the presence of $\ddot{q}$ in the term $\dot{g}$) and achieves perfect cancelation of the gravity term in the link dynamics, through a non-collocated torque at the motor side (De Luca and Flacco 2011). The robot links behave as if there were no gravity acting on the system, whereas the motor dynamics

is indeed still influenced. When completing the design with (5), no strictly positive lower bounds are needed for global asymptotic stability, i.e., $K_P > 0$ and $K > 0$ are now sufficient.

Additional feedback from the full robot state $(q, \dot{q}, \theta, \dot{\theta})$, measured or reconstructed through dynamic observers, can provide faster and damped transient responses. This solution is particularly convenient when a joint torque sensor measuring τ_J is available (*torque-controlled* robots). Using

$$\tau = K_P(\theta_d - \theta) - K_D\dot{\theta} + K_T(g(q_d) - \tau_J) - K_S\dot{\tau}_J + g(q_d), \quad (7)$$

the four diagonal gain matrices can be given a special structure so that asymptotic stability is automatically guaranteed (Albu-Schäffer and Hirzinger 2001).

Trajectory Tracking

Let a desired sufficiently smooth trajectory $q_d(t)$ be specified for the robot links over a finite or infinite time interval. The control objective is to asymptotically stabilize the trajectory tracking error $e = q_d(t) - q(t)$ to zero, starting from a generic initial robot state. Assuming that $q_d(t)$ is four times continuously differentiable, a torque input profile $\tau_d(t) = \tau_d(q_d, \dot{q}_d, \ddot{q}_d, \dddot{q}_d, \ddot{q}_d)$ can be derived from the dynamic model (1) and (2) so as to reproduce exactly the desired trajectory, when starting from matched initial conditions. A local solution to the trajectory tracking problem is provided by the combination of such feedforward term $\tau_d(t)$ with a stabilizing linear feedback from the partial or full robot state; see Eqs. (6) or (7).

When the joint stiffness is large enough, one can take advantage of the system being *singularly perturbed*. A control law τ_s designed for the rigid robot will deal with the slow dynamics, while a relatively simple action τ_f is used to stabilize the fast vibratory dynamics around an invariant manifold associated to the rigid robot control (Spong et al. 1987). This class of composite control laws

has the general form

$$\tau = \tau_s(q, \dot{q}, t) + \epsilon \tau_f(q, \dot{q}, \tau_J, \dot{\tau}_J). \quad (8)$$

When setting $\epsilon = 0$ in Eqs. (3), (4), and (8), the control setup of the equivalent rigid robot is recovered as

$$(M(q) + B)\ddot{q} + n(q, \dot{q}) = \tau_s. \quad (9)$$

Though more complex, the best performing trajectory tracking controller for the general case is based on *feedback linearization*. Spong (1987) has shown that the nonlinear state feedback

$$\tau = \alpha(q, \dot{q}, \ddot{q}, \dddot{q}) + \beta(q)v, \quad (10)$$

with

$$\begin{aligned} \alpha &= M(q)\ddot{q} + n(q, \dot{q}) \\ &\quad + BK^{-1}((\ddot{M}(q) + K)\ddot{q} + 2\dot{M}(q)\ddot{q} \\ &\quad + \ddot{n}(q, \dot{q})) \\ \beta &= BK^{-1}M(q), \end{aligned}$$

leads globally to the closed-loop linear system

$$q^{[4]} = v, \quad (11)$$

i.e., to decoupled chains of four input-output integrators from each auxiliary input v_i to each link position output q_i , for $i = 1, \dots, n$. The control design is then completed on the linear SISO side, by forcing the trajectory tracking error to be *exponentially stable* with an arbitrary decaying rate. The control law (10) is expressed as a function of the *linearizing* coordinates $(q, \dot{q}, \ddot{q}, \ddot{q})$ (up to the link jerk), which can be however rewritten in terms of the original state $(q, \dot{q}, \theta, \dot{\theta})$ using the dynamic model equations. This fundamental result is the direct extension of the so-called “computed torque” method for rigid robots.

Robots with Flexible Links

Dynamic Modeling

For the dynamic modeling of a single flexible link, the distributed nature of structural flexibility can be captured, under suitable assumptions, by partial differential equations (PDE) with associated boundary conditions. A common model is the *Euler-Bernoulli* beam. The link is assumed to be a slender beam, with uniform geometric characteristics and homogeneous mass distribution, clamped at the base to the rigid hub of an actuator producing a torque τ and rotating on a horizontal plane. The beam is flexible in the lateral direction only, being stiff with respect to axial forces, torsion, and bending due to gravity. Deformations are small and are in the elastic domain. The physical parameters of interest are the linear density ρ of the beam, its flexural rigidity EI , the beam length ℓ , and the hub inertia I_h (with $I_t = I_h + \rho\ell^3/3$). The equations of motion combine lumped and distributed parameter parts, with the hub rotation $\theta(t)$ and the link deformation $w(x, t)$, being $x \in [0, \ell]$ the position along the link. From Hamilton principle, we obtain

$$I_t \ddot{\theta}(t) + \rho \int_0^\ell x \ddot{w}(x, t) dx = \tau(t) \quad (12)$$

$$EI w''''(x, t) + \rho \ddot{w}(x, t) + \rho x \ddot{\theta}(t) = 0 \quad (13)$$

$$\begin{aligned} w(0, t) &= w'(0, t) = 0, \\ w''(\ell, t) &= w'''(\ell, t) = 0, \end{aligned} \quad (14)$$

where a prime denotes partial derivative w.r.t. to space. Equation (14) are the clamped-free boundary conditions at the two ends of the beam (no payload is present at the tip).

For the analysis of this self-adjoint PDE problem, one proceeds by separation of variables in space and time, defining

$$w(x, t) = \phi(x)\delta(t) \quad \theta(t) = \alpha(t) + k\delta(t), \quad (15)$$

where $\phi(x)$ is the link spatial deformation, $\delta(t)$ is its time behavior, $\alpha(t)$ describes the angular motion of the instantaneous center of mass of the beam, and k is chosen so as to satisfy (12) for $\tau = 0$. Being system (12), (13), and (14) linear, nonrational transfer functions can be derived in the Laplace transform domain between the input torque and some relevant system output, e.g., the angular position of the hub or of the tip of the beam (Kano 1990). The PDE formalism provides also a convenient basis for analyzing distributed sensing, feedback from strain sensors (Luo 1993), or even distributed actuation with piezo-electric devices placed along the link.

The transcendental characteristic equation associated to the spatial part of the solution to Eqs. (12), (13), and (14) is

$$\begin{aligned} I_h \gamma^3 (1 + \cos(\gamma\ell) \cosh(\gamma\ell)) \\ + \rho (\sin(\gamma\ell) \cosh(\gamma\ell) - \cos(\gamma\ell) \sinh(\gamma\ell)) = 0. \end{aligned} \quad (16)$$

When the hub inertia $I_h \rightarrow \infty$, the second term can be neglected and the characteristic equation collapses into the so-called *clamped* condition. Equation (16) has an infinite but countable number of positive real roots γ_i , with associated eigenvalues of resonant frequencies $\omega_i = \gamma_i^2 \sqrt{EI/\rho}$ and orthonormal eigenvectors $\phi_i(x)$, which are the natural deformation shapes of the beam (Barbieri and Özgüner 1988). A finite-dimensional dynamic model is obtained by truncation to a finite number m_e of eigenvalues/shapes. From

$$w(x, t) = \sum_{i=1}^{m_e} \phi_i(x) \delta_i(t) \quad (17)$$

we get

$$\begin{aligned} I_t \ddot{\alpha}(t) &= \tau(t) \\ \ddot{\delta}_i(t) + \omega_i^2 \delta_i(t) &= \phi_i'(0) \tau(t), \\ i &= 1, \dots, m_e, \end{aligned} \quad (18)$$

where the rigid body motion (top equation) appears as decoupled from the flexible dynamics,

thanks to the choice of variable α rather than θ . Modal damping can be added on the left-hand sides of the lower equations through terms $2\zeta_i\omega_i\dot{\delta}_i$ with $\zeta_i \in [0, 1]$. The angular position of the motor hub at the joint is given by

$$\theta(t) = \alpha(t) + \sum_{i=1}^{m_e} \phi'_i(0)\delta_i(t), \quad (19)$$

while the tip angular position is

$$y(t) = \alpha(t) + \sum_{i=1}^{m_e} \frac{\phi_i(\ell)}{\ell} \delta_i(t). \quad (20)$$

The *joint-level* transfer function $p_{\text{joint}}(s) = \theta(s)/\tau(s)$ will always have relative degree two and only minimum phase zeros. On the other hand, the *tip-level* transfer function $p_{\text{tip}}(s) = y(s)/\tau(s)$ will contain non-minimum phase zeros. This basic difference in the pattern of the transmission zeros is crucial for motion control design.

In a simpler modeling technique, a specified class of spatial functions $\phi_i(x)$ is assumed for describing link deformation. The functions need to satisfy only a reduced set of geometric boundary conditions (e.g., *clamped* modes at the link base), but otherwise no dynamic equations of motion such as (13). The use of finite-dimensional expansions like (17) limits the validity of the resulting model to a maximum frequency. This truncation must be accompanied by suitable filtering of measurements and of control commands, so as to avoid or limit spillover effects (Balas 1978).

In the dynamic modeling of robots with n flexible links, the resort to *assumed modes* of link deformation becomes unavoidable. In practice, some form of approximation and a finite-dimensional treatment is necessary. Let θ be the n -vector of joint variables describing the rigid motion and δ be the m -vector collecting the deformation variables of all flexible links. Following a Lagrangian formulation, the dynamic model with clamped modes takes the general form (Book 1984)

$$\begin{pmatrix} \mathbf{M}_{\theta\theta}(\theta, \delta) & \mathbf{M}_{\theta\delta}(\theta, \delta) \\ \mathbf{M}_{\theta\delta}^T(\theta, \delta) & \mathbf{M}_{\delta\delta}(\theta, \delta) \end{pmatrix} \begin{pmatrix} \ddot{\theta} \\ \ddot{\delta} \end{pmatrix} + \begin{pmatrix} \mathbf{n}_\theta(\theta, \delta, \dot{\theta}, \dot{\delta}) \\ \mathbf{n}_\delta(\theta, \delta, \dot{\theta}, \dot{\delta}) \end{pmatrix} + \begin{pmatrix} \mathbf{0} \\ \mathbf{D}\dot{\delta} + \mathbf{K}\delta \end{pmatrix} = \begin{pmatrix} \boldsymbol{\tau} \\ \mathbf{0} \end{pmatrix}, \quad (21)$$

where the positive definite, symmetric inertia matrix $\mathcal{M}$ of the complete robot and the Coriolis, centrifugal, and gravitational terms $\mathbf{n}$ have been partitioned in blocks of suitable dimensions, $\mathbf{K} > 0$ and $\mathbf{D} \geq 0$ are the robot link stiffness and damping matrices, and $\boldsymbol{\tau}$ is the n -vector of actuating torques.

The dynamic model (21) shows the general couplings existing between nonlinear rigid body motion and linear flexible dynamics. In this respect, the linear model (18) of a single flexible link is a remarkable exception.

The choice of specific assumed modes may simplify the blocks of the robot inertia matrix, e.g., orthonormal modes used for each link induce a decoupled structure of the diagonal inertia subblocks of $\mathbf{M}_{\delta\delta}$. Quite often the total kinetic energy of the flexible robot is evaluated only in the undeformed configuration $\delta = \mathbf{0}$. With this approximation, the inertia matrix becomes independent of δ , and so the velocity terms in the model. Furthermore, due to the hypothesis of small deformation of each link, the dependence of the gravity term in the lower component $\mathbf{n}_\delta$ is only a function of θ .

The validation of (21) goes through the experimental identification of the relevant dynamic parameters. Besides those inherited from the rigid case (mass, inertia, etc.), also the set of structural resonant frequencies and associated deformation profiles should be identified.

Control of Joint-Level Motion

When the target variables to be controlled are defined at the joint level, the control problem for robots with flexible links is similar to that of robots with flexible joints. As a matter of fact, the models (1), (2), and (21) are both *passive* systems with respect to the output θ ; see (19)

in the scalar case. For instance, regulation is achieved by a PD action with constant gravity compensation, using a control law of the form (6) without the need of feeding back link deformation variables (De Luca and Siciliano 1993a). Similarly, stable tracking of a joint trajectory $\theta_d(t)$ is obtained by a singular perturbation control approach, with flexible modes dynamics acting at multiple time scales with respect to rigid body motion (Siciliano and Book 1988), or by an inversion-based control (De Luca and Siciliano 1993b), where input-output (rather than full state) exact linearization is realized and the effects of link flexibility are canceled on the motion of the robot joints. While vibrational behavior will still affect the robot at the level of end-effector motion, the closed-loop dynamics of the δ variables is stable, and link deformations converge to a steady-state constant value (zero in the absence of gravity), thanks to the intrinsic damping of the mechanical structure. Improved transients are indeed obtained by active modal damping control (Cannon and Schmitz 1984).

A control approach specifically developed for the rest-to-rest motion of flexible mechanical systems is *command shaping* (Singer and Seering 1990). The original command designed to achieve a desired motion for a rigid robot is convolved with suitable signals delayed in time, so as to cancel (or reduce to a minimum) the effects of the excited vibration modes at the time of motion completion. For a single slewing link with linear dynamics, as in (18), the rest-to-rest input command is computed in closed form by using impulsive signals and can be made robust via an over-parameterization.

Control of Tip-Level Motion

The design of a control law that allows asymptotic tracking of a desired trajectory for the end effector of a robot with flexible links needs to face the unstable zero dynamics associated to the problem. In the linear case of a single flexible link, this is equivalent to the presence of non-minimum phase zeros in the transfer function to the tip output (20). Direct inversion of the input-output map leads to instability, due to cancelation of non-minimum phase zeros by unstable poles,

with link deformation growing unbounded and control saturations.

The solution requires instead to determine the unique reference state trajectory of the flexible structure that is associated to the desired tip trajectory and has *bounded* deformation. Based on regulation theory, the control law will be the superposition of a nominal feedforward action, which keeps the system along the reference state trajectory (and thus the output on the desired trajectory), and of a stabilizing feedback that reduces the error with respect to this state trajectory to zero without resorting to dangerous cancelations.

In general, computing such a control law requires the solution of a set of nonlinear partial differential equations. However, in the case of a single flexible link with linear dynamics, the feedforward profile is simply derived by an inversion defined in the *frequency domain* (Bayo 1987). The desired tip acceleration $\ddot{y}_d(t)$, $t \in [0, T]$, is considered as part of a rest-to-rest periodic signal, with zero mean value and zero integral. The procedure, implemented efficiently using fast Fourier transform on discrete-time samples, will automatically generate bounded time signals only. The resulting unique torque profile $\tau_d(t)$ will be a *noncausal* command, anticipating the actual start of the output trajectory at $t = 0$ (so as to *precharge* the link to the correct initial deformation) and ending after $t = T$ (to *discharge* the residual link deformation and recover the final rest configuration).

The same result was recovered by Kwon and Book (1994) in the time domain, by forward integrating in time the stable part of the inverse system dynamics and backward integrating the unstable part. An extension to the multi-link nonlinear case uses an iterative approach on repeated linear approximations of the system along the nominal trajectory (Bayo et al. 1989).

Summary and Future Directions

The presence of mechanical flexibility in the joints and the links of multi-dof robots poses challenging control problems. Control designs

take advantage or are limited by some system-level properties. Robots with flexible joints are passive systems at the level of motor outputs, have no zero dynamics associated to the link position outputs, and are always feedback linearizable systems. Robots with flexible links are still passive for joint-level outputs, but cannot be feedback linearized in general, and have unstable zero dynamics (non-minimum phase zeros in the linear case) when considering the end-effector position as controlled output.

State-of-the-art control laws address regulation and trajectory tracking tasks in a satisfactory way, at least in nominal conditions and under full-state feedback. Current research directions are aimed at achieving robustness to model uncertainties and external disturbances (with adaptive, learning, or iterative schemes) and further exploit the design of control laws under limited measurements and noisy sensing. Beyond free motion tasks, an accurate treatment of interaction tasks with the environment, requiring force or impedance controllers, is still missing for flexible robots. In this respect, passivity-based control approaches that do not necessarily operate dynamic cancelations may take advantage of the existing compliance, trading off between improved energy efficiency and some reduction in nominal performance.

Another avenue of research is to exploit the natural behavior of flexible robots, modifying by feedback the minimum amount of system dynamics needed in order to achieve the control target. In a sense, this approach is placed at the crossroad between model-based feedback linearization and passivity-based control. A first example is the gravity cancelation method of De Luca and Flacco (2010), which makes a robot having joints with (constant or variable) flexibility that moves under gravity feedback equivalent to the same robot without gravity. Such an *elastic structure preserving* concept has been expanded by introducing a number of similar control schemes, e.g., for link damping injection or trajectory tracking (Keppler et al. 2018). Recent results along this line have been obtained also for a class of soft continuous robot with distributed flexibility. Model-based controllers for tracking trajectories

in free space and for following contact surfaces can be designed so as to preserve the natural softness of the robot body and adapt to interactions with an unstructured environment (Della Santina et al. 2018).

Often seen as a limiting factor for performance, the presence of elasticity is now becoming an explicit advantage for safe physical human-robot interaction and for locomotion. The next generation of lightweight robots and humanoids will make use of flexible joints and also of a compact actuation with online controlled variable joint stiffness, an area of active research.

Flocking in Networked Systems

Ali Jadbabaie

University of Pennsylvania, Philadelphia, PA, USA

Abstract

Flocking is a collective behavior exhibited by many animal species such as birds, insects, and fish. Such behavior is generated by distributed motion coordination through nearest-neighbor interactions. Empirical study of such behavior has been an active research in ecology and evolutionary biology. Mathematical study of such behaviors has become an active research area in a diverse set of disciplines, ranging from statistical physics and computer graphics to control theory, robotics, opinion dynamics in social networks, and general theory of multiagent systems. While models vary in detail, they are all based on local diffusive dynamics that results in emergence of consensus in direction of motion. Flocking is closely related to the notion of consensus and synchronization in multiagent systems, as examples of collective phenomena that emerge in multiagent systems as result of local nearest-neighbor interactions.

Consensus · Dynamics · Flocking · Graph theory · Markov chains · Switched dynamical systems · Synchronization

Flocking or social aggregation is a group behavior observed in many animal species, ranging from various types of birds to insects and fish. The phenomena can be loosely defined as any aggregate collective behavior in parallel rectilinear formation or (in case of fish) in collective circular motion. The mechanisms leading to such behavior have been (and continues to be) an active area of research among ecologists and evolutionary biologists, dating back to the 1950s if not earlier. The engineering interest in the topic is much more recent.

In 1986, Craig Reynolds (1987), a computer graphics researcher, developed a computer model of collective behavior for animated artificial objects called boids. The flocking model for boids was used to realistically duplicate aggregation phenomena in fish flocks and bird schools for computer animation. Reynolds developed a simple, intuitive physics-based model: each boid was a point mass subject to three simple steering forces: alignment (to steer each boid towards the average heading of its *local* flockmates), cohesion (steering to move towards the average position of *local* flockmates), and separation (to avoid crowding local flockmates). The term *local* should be understood as those flockmates who are within each other's influence zone, which could be a disk (or a wide-angle sector of a disk) centered at each boid with a prespecified radius. This simple zone-based model created very realistic flocking behaviors and was used in many animations (Fig. 1). Reynolds' 3 rules of flocking.

Nine years later, in 1995, Vicsek et al. (1995) and coauthors independently developed a model for velocity alignment of self-propelled particles (SPPs) in a square with periodic boundary conditions. SPPs are essentially kinematic particles moving with constant speed and the steering law determines the angle of (what control

theorists call a kinematic, nonholonomic vehicle model). Vicsek et al.'s steering law was very intuitive and simple and was essentially Reynolds' zone-based alignment rule (Vicsek was not aware of Reynolds' result): each particle averages the *angle* of its velocity vector with that of its neighbors (those within a disk of a prespecified distance), plus a noise term used to model inaccuracies in averaging. Once the velocity vector is determined at each time, each particle takes a unit step along that direction, then determining its neighbors again and repeating the protocol.

The simulations were done in a square of unit length with periodic boundary conditions, to simulate infinite space. Vicsek and coauthors simulated this behavior and found that as the density of the particles increased, a preferred direction spontaneously emerged, resulting in a global group behavior with nearly aligned velocity vectors for all particles, despite the fact that the update protocol is entirely local.

With the interest in control theory shifting towards multiagent systems and networked coordination and control, it became clear that the mathematics of how birds flock and fish school and how individuals in a social network reach agreement (even though they are often only influenced by other like-minded individuals) are quite related to the question of how can one engineer a swarm of robots to behave like bird flocks.

These questions have occupied the minds of many researchers in diverse areas ranging from control theory to robotics, mathematics, and computer science. As discussed above, most of the early research, which happened in computer graphics and statistical physics, was on modeling and simulation of collective behavior. Over the past 13 years, however, the focus has shifted to rigorous systems theoretic foundations, leading to what one might call a theory of collective phenomena in multiagent systems. This theory blends dynamical systems, graph theory, Markov chains, and algorithms.

This type of collective phenomena are often modeled as many-degrees-of-freedom (discrete-time or continuous-time) dynamical systems with an additional twist that the interconnection

Flocking in Networked Systems, Fig. 1 Photo from <http://red3d.com/cwr/boids/>

structure between individual dynamical systems changes, since the motion of each node in a flock (or opinion of an individual) is affected primarily by those in each node's *local neighborhood*. The twist here is that the local neighborhood is not fixed: neighbors are defined based on the actual state of the system, for example, in case of Vicsek's alignment rule, as each particle averages its velocity direction with that of its neighbors and then takes a step, the set of its nearest neighbors can change.

Interestingly, very similar models were developed in statistics and mathematical sociology literature to describe how individuals in a social network update their opinions as a function of the opinion of their friends. The first such model goes back to the seminal work of DeGroot (1974) in 1974. DeGroot's model simply described the evolution of a group's scalar opinion as a function of the opinion of their neighbors by an iterative averaging scheme that can be conveniently modeled as a Markov chain. Individuals are represented by nodes of a graph, start from an opinion at time zero, and then are influenced by the people in their social clique. In DeGroot's model though, the network is given exogenously and does not change as a function of the opinions. The model therefore can be analyzed using the celebrated Perron-Frobenius theorem. The evolution of opinions is a discrete dynamic system that corresponds to an averaging map. When the network is fixed and connected (i.e., there is a path from every node to every other node) and agents also include their own opinions in the averaging, the update results in computation of a global weighted average of initial opinions,

where the weight of each initial opinion in the final aggregate is proportional to the "importance" of each node in the network.

The flocking models of Reynolds (1987) and Vicsek et al. (1995), however, have an extra twist: the network changes as opinions are updated. Similarly, more refined sociological models developed over the past decade also capture this endogeneity (Hegselmann and Krause 2002): each individual agent is influenced by others only when their opinion is close to her own. In other words, as opinions evolve, neighborhood structures change as the function of the evolving opinion, resulting in a switched dynamical system in which switching is state dependent.

In a paper in 2003, Jadbabaie and coauthors (2003) studied the Reynolds' alignment rule in the context of Vicsek's model when there is no exogenous noise. To model the endogeneity of the change in neighborhood structure, they developed a model based on repeated local averaging in which the neighborhood structure changes over time and therefore instead of a simple discrete-time linear dynamical system, the model is a discrete linear inclusion or a switched linear system. The question of interest was to determine what regimes of network changes could result in flocking. Clearly, as also DeGroot's model suggests, when the local neighbor structures do not change, connectivity is the key factor for flocking. This is a direct consequence of Perron-Frobenius theory. The result can also be described in terms of directed graphs. What is the equivalent condition in changing networks? Jadbabaie and coauthors show in their paper that indeed connectivity is important, but it need not hold every time: rather,

there needs to be time periods over which the graphs are *connected in time*. More formally, the process of neighborhood changes due to motion in Vicsek's model can be simply abstracted as a graph in which the links "blink" on and off. For flocking, one needs to ensure that there are time periods over which the union of edges (that occur as a result of proximity of particles) needs to correspond to a connected graph and such intervals need to occur infinitely often. It turns out that many of these ideas were developed much earlier in a thesis and following paper by Tsitsiklis (1984) and Tsitsiklis et al. (1986), in the context of distributed and asynchronous computation of global averages in changing graphs, and in a paper by Chatterjee and Seneta (1977), in the context of nonhomogeneous Markov chains. The machinery for proving such a results, however, is classical and has a long history in the theory of inhomogeneous Markov chains, a subject studied since the time of Markov himself, followed by Birkhoff and other mathematicians such as Hajnal, Dobrushin, Seneta, Hatfield, Daubachies, and Lagarias, to name a few.

The interesting twist in analysis of Vicsek's model is that the Euclidean norm of the distance to the globally converged "consensus angle" (or consensus opinion in the case of opinion models) can actually *grow* in a single step of the process; therefore, standard quadratic Lyapunov function arguments which serve as the main tool for analysis of switched linear systems are not suitable for the analysis of such models. However, it is fairly easy to see that under the process of local averaging, the largest value cannot increase and the smallest value cannot decrease. In fact, one can show that if enough connected graphs occur as the result of the switching process, the maximum value will be strictly decreasing and the minimum value will be strictly increasing. The paper by Jadbabaie and coauthors (2003) has lead to a flurry of results in this area over the past decade. One important generalization to the results of Jadbabaie et al. (2003), Tsitsiklis (1984), and Tsitsiklis et al. (1986) came 2 years later in a paper by Moreau (2005), who showed that these results can be generalized to nonlinear

updates and directed graphs. Moreau showed that any dynamic process that assigns a point in the interior of the convex hull of the value of each node and its neighbors will eventually result in agreement and consensus, if and only if the union of graphs from every time step till infinity contains a directed spanning tree (a node who has direct links to every other node).

Some of these results were also extended to the analysis of the Reynolds' model of flocking including the other two behaviors. First, Tanner and coauthors (2003, 2007) showed in a series of papers in 2003 and 2007 that a zone-based model similar to Reynolds can result in flocking for dynamic agents, provided that the graph representing interagent communications stays connected. Olfati-Saber and coauthors (2007) developed similar results with a slightly different model.

Many generalizations and extension for these results exist in a diverse set of disciplines, resulting in a rich theory which has had applications from robotics (such as rendezvous in mobile robots) (Cortés et al. 2006) to mathematical sociology (Hegselmann and Krause 2002) and from economics (Golub and Jackson 2010) to distributed optimization theory (Nedic and Ozdaglar 2009). However, some of the fundamental mathematical questions related to flocking still remain open.

First, most results focus on endogenous models of network change. A notable extension is a paper by Cucker and Smale (2007), in which the authors develop and analyze an endogenous model of flocking that cleverly *smoothens out* the discontinuous change in network structure by allowing each node's influence to decay smoothly as a function of distance.

Recently, in a series of papers, Chazelle has made progress in this arena by using tools from computational geometry and algorithms for analysis of endogenous models of flocking (Chazelle 2012). Chazelle has introduced the notion of the *s-energy* of a flock, which can be thought of as a parameterized family of Lyapunov functions that represent the evolution of global misalignment between flockmates. Via

tools from dynamical systems, computational geometry, combinatorics, complexity theory, and algorithms, Chazelle creates an “algorithmic calculus,” for *diffusive influence systems*: surprisingly, he shows that the orbit or flow of such systems is attracted to a fixed point in the case of undirected graphs and a limit cycle for almost all arbitrarily small random perturbations. Furthermore, the convergence time can also be bounded in both cases and the bounds are essentially optimal. The setup of the diffusive influence system developed by Chazelle creates a near-universal setup for analyzing various problems involving collective behavior in networked multiagent systems, from flocking, opinion dynamics, and information aggregation to synchronization problems.

To make further progress on analysis of what one might call networked dynamical systems (which Chazelle calls influence systems), one needs to combine mathematics of algorithms, complexity, combinatorics, and graphs with systems theory and dynamical systems.

Summary and Future Directions

This article presented a brief summary of the literature on flocking and distributed motion coordination. Flocking is the process by which various species exhibit synchronous collective motion from simple local interaction rules. Motivated by social aggregation in various species, various algorithms have been developed in the literature to design distributed control laws for group behavior in collective robotics and analysis of opinion dynamics in social networks. The models describe each agent as a kinematic or point mass particle that aligns each agent’s direction with that of its neighbors using repeated local averaging of directions. Since the neighborhood structures change due to motion, this results in a distributed switched dynamical system. If a weak notion of connectivity among agents is preserved over time, then agents reach consensus in their direction of motion. Despite the flurry of results in this area, the analysis of this phenomenon that

accounts for endogenous change in dynamics is for the most part open.

Force Control in Robotics

Luigi Villani

Dipartimento di Ingegneria Elettrica e Tecnologie dell'Informazione, Università degli Studi di Napoli Federico II, Napoli, Italy

Abstract

Force control is used to handle the physical interaction between a robot and the environment and also to ensure safe and dependable operation in the presence of humans. The control goal may be that to keep the interaction forces limited or that to guarantee a desired force along the directions where interaction occurs while a desired motion is ensured in the other directions. This entry presents the basic control schemes, focusing on robot manipulators.

Keywords

Compliance control · Constrained motion · Force control · Force/torque sensor · Hybrid force/motion control · Impedance control · Stiffness control

Introduction

Control of the physical interaction between a robot manipulator and the environment is crucial for the successful execution of a number of practical tasks where the robot end effector

has to manipulate an object or perform some operation on a surface. Typical examples in industrial settings include polishing, deburring, machining, or assembly.

During contact, the environment may set constraints on the geometric paths that can be followed by the robot's end effector (kinematic constraints) as in the case of sliding on a rigid surface. In other situations, the interaction occurs with a dynamic environment as in the case of collaboration with a human. In all cases, a pure motion control strategy is not recommended, especially if the environment is stiff.

The higher the environment stiffness and position control accuracy are, the more easily the contact forces may rise and reach unsafe values. This drawback can be overcome by introducing compliance, either in a passive or in an active fashion, to accommodate the robot motion in response to interaction forces.

Passive compliance may be due to the structural compliance of the links, joints, and end effector or to the compliance of the position servo. Soft robot arms with elastic joints or links are purposely designed for intrinsically safe interaction with humans. In contrast, active compliance is entrusted to the control system, denoted *interaction control* or *force control*. In some cases, the measurement of the contact force and moment is required, which is fed back to the controller and used to modify or even generate online the desired motion of the robot (Whitney 1977).

The passive solution is faster than active reaction commanded by a computer control algorithm. However, the use of passive compliance alone lacks of flexibility and cannot guarantee that high contact forces will never occur. Hence, the most effective solution is that of using active force control (with or without force feedback) in combination with some degree of passive compliance.

In general, six force components are required to provide complete contact force information: three translational force components and three torques. Often, a *force/torque sensor* is mounted at the robot wrist (see an example in Fig. 1),

Force Control in Robotics, Fig. 1 Industrial robot with wrist force/torque sensor and deburring tool

but other possibilities exist, for example, force sensors can be placed on the fingertips of robotic hands; also, external forces and moments can be estimated via shaft torque measurements of joint torque sensors.

The force control strategies can be grouped into two categories (Siciliano and Villani 1999): those performing indirect force control and those performing direct force control. The main difference between the two categories is that the former achieve force control via motion control, without explicit closure of a force feedback loop; the latter instead offer the possibility of controlling the contact force and moment to a desired value, thanks to the closure of a force feedback loop.

Modeling

The case of interaction of the end effector of a robot manipulator with the environment is con-

sidered, which is the most common situation in industrial applications.

The end-effector pose can be represented by the position vector p_e and the rotation matrix $\mathbf{R}_e$, corresponding to the position and orientation of a frame attached to the end effector with respect to a fixed-base frame.

The end-effector velocity is denoted by the 6×1 twist vector $\mathbf{v}_e = (\dot{p}_e^T \ \omega_e^T)^T$ where $\dot{p}_e$ is the translational velocity and ω_e is the angular velocity and can be computed from the joint velocity vector $\dot{q}$ using the linear mapping

$$\mathbf{v}_e = \mathbf{J}(q)\dot{q}.$$

The matrix $\mathbf{J}$ is the end-effector Jacobian. For simplicity, the case of nonredundant nonsingular manipulators is considered; therefore, the Jacobian is a square nonsingular matrix.

The force f_e and moment m_e applied by the end effector to the environment are the components of the wrench $h_e = (f_e^T \ m_e^T)^T$. The joint torques τ corresponding to h_e can be computed as

$$\tau = \mathbf{J}^T(q)h_e.$$

It is useful to consider the operational space formulation of the dynamic model of a rigid robot manipulator in contact with the environment (Khatib 1987):

$$\Lambda(q)\dot{\mathbf{v}}_e + \Gamma(q, \dot{q})\mathbf{v}_e + \eta(q) = h_c - h_e, \quad (1)$$

where $\Lambda(q)$ is the 6×6 operational space inertia matrix, $\Gamma(q, \dot{q})$ is the wrench including centrifugal and Coriolis effects, and $\eta(q)$ is the wrench of the gravitational effects. The vector $h_c = \mathbf{J}^{-T}\tau$ is the equivalent end-effector wrench corresponding to the input joint torques τ_c .

Equation (1) can be seen as a representation of the Newton's Second Law of Motion where all the generalized forces acting on the joints of the robot are reported at the end effector.

The full specification of the system dynamics would require also the analytic description of the interaction force and moment h_e . This is a very demanding task from a modeling viewpoint.

The design of the interaction control and the performance analysis are usually carried out under simplifying assumptions. The following two cases are considered:

1. The robot is perfectly rigid, all the compliance in the system is localized in the environment, and the contact wrench is approximated by a linear elastic model.
2. The robot and the environment are perfectly rigid and purely kinematics constraints are imposed by the environment.

It is obvious that these situations are only ideal. However, the robustness of the control should be able to cope with situations where some of the ideal assumptions are relaxed. In that case the control laws may be adapted to deal with nonideal characteristics.

Indirect Force Control

The aim of indirect force control is that of achieving a desired compliant dynamic behavior of the robot's end effector in the presence of interaction with the environment.

Stiffness Control

The simpler approach is that of imposing a suitable static relationship between the deviation of the end-effector position and orientation from a desired pose and the force exerted on the environment, by using the control law

$$h_c = \mathbf{K}_P \Delta x_{de} - \mathbf{K}_D \mathbf{v}_e + \boldsymbol{\eta}(q), \quad (2)$$

where $\mathbf{K}_P$ and $\mathbf{K}_D$ are suitable matrix gains and Δx_{de} is a suitable error between a desired and the actual end-effector position and orientation. The position error component of Δx_{de} can be simply chosen as $p_d - p_e$. Concerning the orientation error component, different choices are possible (Caccavale et al. 1999), which are not all equivalent, but this issue is outside the scope of this entry.

The control input (2) corresponds to a wrench (force and moment) applied to the end effector,

which includes a gravity compensation term $\boldsymbol{\eta}(q)$, a viscous damping term $\mathbf{K}_D \mathbf{v}_e$, and an elastic wrench provided by a virtual spring with stiffness matrix $\mathbf{K}_P$ (or, equivalently, compliance matrix $\mathbf{K}_P^{-1}$) connecting the end-effector frame with a frame of desired position and orientation. This control law is known as *stiffness control* or *compliance control* (Salisbury 1980).

Using the Lyapunov method, it is possible to prove the asymptotic stability of the equilibrium solution of equation

$$\mathbf{K}_P \Delta x_{de} = h_e,$$

meaning that, at steady state, the robot's end effector has a desired elastic behavior under the action of the external wrench h_e . It is clear that, if $h_e \neq \mathbf{0}$, then the end effector deviates from the desired pose, which is usually denoted as *virtual pose*.

Physically, the closed-loop system (1) with (2) can be seen as a 6-DOF nonlinear and configuration-dependent mass-spring-damper system with inertia (mass) matrix $\boldsymbol{\Lambda}(q)$ and adjustable damping $\mathbf{K}_D$ and stiffness $\mathbf{K}_P$, under the action of the external wrench h_e .

Impedance Control

A configuration-independent dynamic behavior can be achieved if the measure of the end-effector force and moment h_e is available, by using the control law, known as *impedance control* (Hogan 1985):

$$h_c = \boldsymbol{\Lambda}(q)\boldsymbol{\alpha} + \boldsymbol{\Gamma}(q, \dot{q})\dot{q} + \boldsymbol{\eta}(q) + h_e,$$

where $\boldsymbol{\alpha}$ is chosen as:

$$\boldsymbol{\alpha} = \dot{\mathbf{v}}_d + \mathbf{K}_M^{-1}(\mathbf{K}_D \Delta \mathbf{v}_{de} + \mathbf{K}_P \Delta x_{de} - h_e).$$

The following expression can be found for the closed-loop system

$$\mathbf{K}_M \Delta \dot{\mathbf{v}}_{de} + \mathbf{K}_D \Delta \mathbf{v}_{de} + \mathbf{K}_P \Delta x_{de} = h_e, \quad (3)$$

representing the equation of a 6-DOF configuration-independent mass-spring-damper system with adjustable inertia (mass) matrix

Force Control in Robotics, Fig. 2 Impedance control

$\mathbf{K}_M$, damping $\mathbf{K}_D$, and stiffness $\mathbf{K}_P$, known as mechanical *impedance*.

A block diagram of the resulting impedance control is sketched in Fig. 2.

The selection of good impedance parameters ensuring a satisfactory behavior is not an easy task and can be simplified under the hypothesis that all the matrices are diagonal, resulting in a decoupled behavior for the end-effector coordinates.

Moreover, the dynamics of the controlled system during the interaction depends on the dynamics of the environment that, for simplicity, can be approximated as a simple elastic law for each coordinate, of the form

$$h_e = k \Delta x_{e0},$$

where $\Delta x_{e0} = x_e - x_0$, while x_0 and k are the undeformed position and the stiffness coefficient of the spring, respectively.

In the above hypotheses, the transient behavior of each component of Eq. (3) can be set by assigning the natural frequency and damping ratio with the relations

$$\omega_n = \sqrt{\frac{k_P + k}{k_M}}, \quad \zeta = \frac{1}{2} \frac{k_D}{\sqrt{k_M(k_P + k)}}.$$

Hence, if the gains are chosen so that a given natural frequency and damping ratio are ensured during the interaction (i.e., for $k \neq 0$), a smaller natural frequency with a higher damping ratio will be obtained when the end effector moves in free space (i.e., for $k = 0$). As for the steady-state performance, the end-effector error and the interaction force for the generic component are

$$\Delta x_{de} = \frac{k}{(k_P + k)} \Delta x_{do}, \quad h = \frac{k_P k}{k_P + k} \Delta x_{do},$$

showing that, during interaction, the contact force can be made small at the expense of a large position error in steady state, as long as the robot stiffness k_P is set low with respect to the stiffness of the environment k and vice versa.

Direct Force Control

Indirect force control does not require explicit knowledge of the environment, although to achieve a satisfactory dynamic behavior, the control parameters have to be tuned for a particular task. On the other hand, a model of the interaction task is usually required for the synthesis of direct force control algorithms.

In the following, it is assumed that the environment is rigid and frictionless and imposes kinematic constraints to the robot's end-effector motion (Mason 1981). These constraints reduce the dimension of the space of the feasible end-effector velocities and of the contact forces and moments. In detail, in the presence of m independent constraints ($m < 6$), the end-effector velocity belongs to a subspace of dimension $6 - m$, while the end-effector wrench belongs to a subspace of dimension m and can be expressed in the form

$$\mathbf{v}_e = \mathbf{S}_v(q)\mathbf{v}, \quad \mathbf{h}_e = \mathbf{S}_f(q)\boldsymbol{\lambda}$$

where $\mathbf{v}$ is a suitable $(6 - m) \times 1$ vector and $\boldsymbol{\lambda}$ is a suitable $m \times 1$ vector. Moreover, the subspaces of forces and velocity are *reciprocal*, i.e.:

$$\mathbf{h}_e^T \mathbf{v}_e = 0, \quad \mathbf{S}_f^T(q)\mathbf{S}_v(q) = \mathbf{0}.$$

The concept of reciprocity expresses the physical fact that, in the hypothesis of rigid and frictionless contact, the wrench does not cause any work against the twist.

An interaction task can be assigned in terms of a desired end-effector twist $\mathbf{v}_d$ and wrench $\mathbf{h}_d$ that are computed as:

$$\mathbf{v}_d = \mathbf{S}_v \mathbf{v}_d, \quad \mathbf{h}_d = \mathbf{S}_f \boldsymbol{\lambda}_d,$$

by specifying vectors $\boldsymbol{\lambda}_d$ and $\mathbf{v}_d$.

In many robotic tasks it is possible to set an orthogonal reference frame, usually referred as *task frame* (De Schutter and Van Brussel 1988), in which the matrices $\mathbf{S}_v$ and $\mathbf{S}_f$ are constant. Moreover, the interaction task is specified by assigning a desired force/torque or a desired linear/angular velocity along/about each of the frame axes.

An example of task frame definition and task specification is given below.

Peg-in-Hole: The goal of this task is to push the peg into the hole while avoiding wedging and jamming. The peg has two degrees of motion freedom; hence, the dimension of the velocity-controlled subspace is $6 - m = 2$, while the dimension of the force-controlled subspace is

Force Control in Robotics, Fig. 3 Insertion of a cylindrical peg into a hole

$m = 4$. The task frame can be chosen as shown in Fig. 3, and the task can be achieved by assigning the following desired forces and torques:

- Zero forces along the x_t and y_t axes
- Zero torques about the x_t and y_t axes and the desired velocities
- A nonzero linear velocity along the z_t -axis
- An arbitrary angular velocity about the z_t -axis

The task continues until a large reaction force in the z_t direction is measured, indicating that the peg has hit the bottom of the hole, not represented in the figure. Hence, the matrices $\mathbf{S}_f$ and $\mathbf{S}_v$ can be chosen as

$$\mathbf{S}_f = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad \mathbf{S}_v = \begin{pmatrix} 0 & 0 \\ 0 & 0 \\ 1 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 1 \end{pmatrix}.$$

The task frame can be chosen attached either to the end effector or to the environment.

Hybrid Force/Motion Control

The reciprocity of the velocity and force subspaces naturally leads to a control approach, known as *hybrid force/motion control* (Raibert and Craig 1981; Yoshikawa 1987), aimed at

controlling simultaneously both the contact force and the end-effector motion in two reciprocal subspaces.

The reduced order dynamics of the robot with kinematic constraints is described by $6 - m$ second-order equations

$$\mathbf{A}_v(q)\dot{\mathbf{v}} = \mathbf{S}_v^T [h_c - \boldsymbol{\mu}(q, \dot{q})],$$

where $\mathbf{A}_v = \mathbf{S}_v^T \mathbf{A} \mathbf{S}_v$ and $\boldsymbol{\mu}(q, \dot{q}) = \boldsymbol{\Gamma}(q, \dot{q})\mathbf{v}_e + \boldsymbol{\eta}(q)$, assuming constant matrices $\mathbf{S}_v$ and $\mathbf{S}_f$. Moreover, the vector $\boldsymbol{\lambda}$ can be computed as

$$\boldsymbol{\lambda} = \mathbf{S}_f^\dagger(q)[h_c - \boldsymbol{\mu}(q, \dot{q})],$$

revealing that the contact force is a constraint force which instantaneously depends on the applied input wrench h_c .

An inverse-dynamics inner control loop can be designed by choosing the control wrench h_c as

$$h_c = \mathbf{A}(q)\mathbf{S}_v\boldsymbol{\alpha}_v + \mathbf{S}_f f_\lambda + \boldsymbol{\mu}(q, \dot{q}),$$

where $\boldsymbol{\alpha}_v$ and f_λ are properly designed control inputs, which leads to the equations

$$\dot{\mathbf{v}} = \boldsymbol{\alpha}_v, \quad \dot{\boldsymbol{\lambda}} = f_\lambda,$$

showing a complete decoupling between motion control and force control.

Then, the desired force $\boldsymbol{\lambda}_d(t)$ can be achieved by setting

$$f_\lambda = \boldsymbol{\lambda}_d(t),$$

but this choice is very sensitive to disturbance forces, since it contains no force feedback. Alternative choices are

$$f_\lambda = \boldsymbol{\lambda}_d(t) + \mathbf{K}_{P\lambda}[\boldsymbol{\lambda}_d(t) - \boldsymbol{\lambda}(t)],$$

or

$$f_\lambda = \boldsymbol{\lambda}_d(t) + \mathbf{K}_{I\lambda} \int_0^t [\boldsymbol{\lambda}_d(\tau) - \boldsymbol{\lambda}(\tau)] d\tau,$$

where $\mathbf{K}_{P\lambda}$ and $\mathbf{K}_{I\lambda}$ are suitable positive-definite matrix gains. The proportional feedback is able to

reduce the force error due to disturbance forces, while the integral action is able to compensate for constant bias disturbances.

Velocity control is achieved by setting

$$\begin{aligned} \boldsymbol{\alpha}_v &= \dot{\mathbf{v}}_d(t) + \mathbf{K}_{Pv}[\mathbf{v}_d(t) - \mathbf{v}(t)] \\ &+ \mathbf{K}_{Iv} \int_0^t [\mathbf{v}_d(\tau) - \mathbf{v}(\tau)] d\tau, \end{aligned}$$

where $\mathbf{K}_{Pv}$ and $\mathbf{K}_{Iv}$ are suitable matrix gains. It is straightforward to show that asymptotic tracking of $\mathbf{v}_d(t)$ and $\dot{\mathbf{v}}_d(t)$ is ensured with exponential convergence for any choice of positive-definite matrices $\mathbf{K}_{Pv}$ and $\mathbf{K}_{Iv}$.

Notice that the implementation of force feedback requires the computation of vector $\boldsymbol{\lambda}$ from the measurement of the end-effector wrench h_e as $\mathbf{S}_f^\dagger \mathbf{v}_e$, being $\mathbf{S}_f^\dagger$ a suitable pseudoinverse of matrix $\mathbf{S}_f$. Analogously, vector $\mathbf{v}$ can be computed from $\mathbf{v}_e$ as $\mathbf{S}_v^\dagger \mathbf{v}_e$.

The hypothesis of rigid contact can be removed, and this implies that along some directions both motion and force are allowed, although they are not independent. Hybrid force/motion control schemes can be defined also in this case Villani and De Schutter (2008).

Summary and Future Directions

This entry has sketched the main approaches to force control in a unifying perspective. However, there are many aspects that have not been considered here. The two major paradigms of force control (impedance and hybrid force/motion control) are based on several simplifying assumptions that are only partially satisfied in practical implementations and that have been partially removed in more advanced control methods.

Notice that the performance of a force-controlled robotic system depends on the interaction with a changing environment which is very difficult to model and identify correctly. Hence, the standard performance indices used to evaluate a control system, i.e., stability, bandwidth, accuracy, and robustness, cannot

be defined by considering the robotic system alone, as for the case of robot motion control, but must be always referred to the particular contact situation at hand.

Force control in industrial applications can be considered as a mature technology, although, for the reason explained above, standard design methodologies are not yet available. Force control techniques are employed also in medical robotics, haptic systems, telerobotics, humanoid robotics, micro-robotics, and nano robotics. An interesting field of application is related to human-centered robotics, where control plays a key role to achieve adaptability, reaction capability, and safety. Robots and biomechatronic systems based on the novel variable impedance actuators, with physically adjustable compliance and damping, capable to react softly when touching the environment, necessitate the design of specific control laws. The combined use of exteroceptive sensing (visual, depth, proximity, force, tactile sensing) for reactive control in the presence of uncertainty represents another challenging research direction.

Formal Methods for Controlling Dynamical Systems

Calin Belta

Mechanical Engineering, Boston University,
Boston, MA, USA

Abstract

In control theory, complicated dynamics such as systems of (nonlinear) differential equations are mostly controlled to achieve stability. This fundamental property, which can be with respect to a desired operating point or a prescribed trajectory, is often linked with optimality, which requires minimization of a certain cost along the trajectories of a stable system. In formal methods, rich specifications, such as formulas of temporal logics, are checked against simple models of software programs and digital circuits, such as finite transition systems. With the development and integration of cyber physical and safety critical systems, there is an increasing need for computational tools for verification and control of complex systems from rich, temporal logic specifications. The current approaches to formal synthesis of (optimal) control strategies for dynamical systems can be roughly divided in two classes: abstraction-based and optimization-based methods. In this entry, we provide a short overview of these techniques.

Keywords

Formal verification · Model checking ·
Hybrid systems · Optimal control

Introduction

Temporal logics, such as computation tree logic (CTL) and linear temporal logic (LTL), have been customarily used to specify the correctness of computer programs and digital circuits modeled as finite-state transition systems. The problem of analyzing such a model against a temporal

logic formula, known as formal analysis or model checking, has received a lot of attention during the past 40 years, and several efficient algorithms and software tools are available. The formal synthesis problem, in which the goal is to design or control a system from a temporal logic specification, has not been studied extensively until a few years ago.

Control and optimal control are mature research areas with many applications. They cover a large spectrum of systems, including (weighted) finite deterministic transition systems (i.e., graphs for which available transitions can be deterministically chosen at every node), finite purely nondeterministic systems (where an action at a state enables several transitions and their probabilities are not known), finite Markov decision processes (MDP), and systems with infinite state and control sets. For the latter, optimal control problems usually involve costs penalizing the deviation of the state from a reference trajectory and the control effort.

The connection between (optimal) control and formal methods is an intriguing problem with potentially high impact in several applications. By combining these two seemingly unrelated areas, the goal is to control the behavior of a system subject to correctness constraints. Consider, for example, an autonomous vehicle involved in a persistent surveillance mission in a disaster relief application, where dynamic service requests can only be sensed locally in a neighborhood around the vehicle (see Fig. 1). The goal is to accomplish the mission while at the same time maximizing the likelihood of servicing the local requests and possibly minimizing the energy spent during the motion. The correctness requirement can be expressed as a temporal logic formula (see the caption of Fig. 1), while the resource constraints translate to minimizing a cost over the feasible trajectories of the vehicle.

Formal Synthesis of Control Strategies

Current works on combining control and formal methods can be roughly divided into two

Formal Methods for Controlling Dynamical Systems,

Fig. 1 (a) An autonomous air vehicle is deployed from a high level, temporal logic global specification over a set of static, known requests (photo and upload) occurring at the regions of a known environment, e.g., “Keep taking photos and upload current photo before taking another photo.” This specification translates to the following LTL formula: $\mathbf{GF} \text{ photo} \wedge \mathbf{G} (\text{photo} \rightarrow (\text{photo U} (\neg \text{photo U upload})))$, where $\mathbf{G}$, $\mathbf{F}$, and $\mathbf{U}$ are the temporal operators Globally (Always), Future (Eventually), and Until; $\wedge$, $\rightarrow$, $\neg$ are Boolean operators for conjunction, implication, and negation, respectively. While moving in the environment, the vehicle can locally sense dynamically changing events, such as survivors, and fires, which generate (local) service

requests, and unsafe areas, which need to be avoided. The goal is to accomplish the global mission while at the same time maximizing the likelihood of servicing the local requests and staying away from unsafe areas. (b) By using an accurate quad-rotor kinematic model, input-output linearizations/flat outputs, precise state information from a motion capture system, and control-to-facet results for linear and multi-affine systems, this problem can be (conservatively) mapped to a control problem for a finite transition system. This can be deterministic or non-deterministic if single-facet or multiple-facet controllers in the output space are used, respectively. (Example adapted from Ulusoy and Belta 2014)

main classes: automata-based methods and optimization-based methods.

Automata-Based Methods

Automata-based methods are based on the observation that a temporal logic formula, such as an LTL formula, can be mapped to an automaton in such a way that the language accepted by the automaton is exactly the language satisfying the formula. Depending on the desired expressivity of the specification language, these automata can be well-known finite state automata (FSA) (the acceptance condition is reaching a set of final states), Büchi automata (the acceptance condition is reaching a set of final states infinitely often), or, in the most general case, Rabin automata (the acceptance condition is to visit a set of “good” states infinitely often and a set of “bad” states finitely many times). For finite systems, the control problem reduces to a game on the product between a system, such as a transition

system or an MDP, and the automaton obtained from the specification. The winning condition, which ensures correctness, is the Rabin (Büchi, FSA) acceptance condition of the automaton. The cost can be average reward/cost per stage and adapted objectives that reflect the semantics of the temporal logic, such as average reward/cost per cycle.

For infinite systems, automata-based approaches are, in general, hierarchical, two-level methods. The bottom level is a continuous-to-continuous abstraction procedure, in which the possibly large state space and complex dynamics are mapped to a low-dimensional output space with simple dynamics. The most used techniques are input-output linearization and differential flatness. For a differentially flat system, its state and control variables can be expressed as a function of its outputs and its derivatives. The top level is a partition-based, continuous-to-discrete abstraction procedure, in which the output and control

spaces are partitioned. The partition can be driven by the specification or by a prescribed accuracy of the approximation. The quotient of the partition is a finite system that is in some way equivalent with the original, infinite system. The most used notion of equivalence is bisimulation. An example is shown in Fig. 1. The 12-dimensional quad-rotor dynamics of the quad-rotor shown in the left are differentially flat with four flat outputs (position and yaw), and up to four derivatives of the flat output are necessary to compute the original state and input. A two-dimensional section of the partition of the four-dimensional output space is shown on the right, together with the assignment of a vector field in two adjacent cells. Note that the dynamics corresponding to these vector fields “treat” all the states in a cell “in the same way”: in the cell on the left, all the states will leave in finite time through the right facet; in the cell on the right, all states will stay inside for all times. Informally, these correspond to the bisimilarity equivalence mentioned above. The quotient of the partition is a finite transition system that is controlled from the temporal logic specification. The cost can penalize the execution time, travelled distance, etc.

The method described above is conservative. If a solution (of the automaton game) is not found at the top level, this does not mean that a controller does not exist for the original continuous system. Intuitively, the partition, and therefore the abstraction, might be too rough. Conservativeness can be reduced by refining the partition. Numerous partition techniques that exploit the connection between the dynamics of the system and the geometry of the partition have been proposed. An example is shown in Fig. 2. An example illustrating the compromise between correctness and optimality is shown in Fig. 3.

The expensive process of constructing the abstraction can be avoided for both deterministic and stochastic systems. Specifically, a dynamic programming problem can be formulated over the product of the continuous-time, continuous-state system, and the specification automaton. Approximate dynamic programming (ADP) approaches have been shown to work for both

linear and nonlinear systems. Sampling-based policy iteration has also been used for optimal planning for a subclass of LTL specifications.

Optimization-Based Methods

There are roughly two classes of optimization-based methods for formal synthesis: mixed integer programming (MIP) methods and control barrier functions (CBF) methods.

Central to the MIP-based methods are temporal logics with semantics over finite-time signals, such as signal temporal logic (STL) and metric temporal logic (MTL). For simplicity, in this article we focus on STL. The main difference between STL and LTL (see the caption of Fig. 1 for an example of an LTL formula) is that STL temporal operators are explicit (see Fig. 4 for an example of an STL formula). In addition to Boolean semantics, in which signals either satisfy or violate a formula, STL has quantitative semantics, which allow to assess the robustness of satisfaction. Specifically, given a formula ϕ and a signal x , the robustness $\rho(\phi, x)$ quantifies how well x satisfies ϕ . The more x satisfies ϕ , the larger $\rho(\phi, x)$ is (if x satisfies ϕ in Boolean semantics, then $\rho(\phi, x) > 0$). The more x violates ϕ , the smaller $\rho(\phi, x)$ is (if x violates ϕ in Boolean semantics, then $\rho(\phi, x) < 0$).

It can be shown that Boolean satisfaction of STL (MTL) formulas over linear predicates in the state x of a system can be mapped to the feasibility part of a mixed integer linear program (MILP) (i.e., a set of linear equalities and inequalities over the state and an additional set of integers). This observation implies that controlling a linear (or almost linear, such as piecewise affine, mixed logical, etc.) system, such that a linear or quadratic cost is optimized while satisfying STL formulas over linear predicates over its state, maps to solving a mixed integer linear program (MILP) or mixed integer quadratic program (MIQP), for which there exist computationally efficient solvers.

Moreover, it can be shown that the robustness function ρ is linear in state and the additional integer variables. Therefore, if robustness is

Formal Methods for Controlling Dynamical Systems,

Fig. 2 A discrete-time double integrator system $x[t + 1] = Ax[t] + Bu[t]$, with $A = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}$, $B = \begin{bmatrix} 0.5 & 1 \end{bmatrix}$, and $u \in [-2, 2]$, moving in a planar environment (a) partitioned into $X_1, X_2, \dots, X_{13}$ is required to satisfy the following specification: “Visit region $\mathbb{A} = X_2$ or region $\mathbb{B} = X_9$, and then the target region $\mathbb{T} = X_7$, while always avoiding obstacles $\mathbb{O}_1 = X_{11}$ and $\mathbb{O}_2 = X_{12}$, which translates to the syntactically co-safe LTL (scLTL) formula: $((\neg \mathbb{O}_1 \wedge \neg \mathbb{O}_2) \mathbf{U} \mathbb{T}) \wedge (\neg \mathbf{T} \mathbf{U} (\mathbb{A} \vee \mathbb{B}))$. Iterations 50, 80, and 108 of an automata-guided iterative partitioning procedure for the computation of the maximal

set of satisfying initial states (and corresponding control strategies) are shown in (b), (c), and (d), respectively (the sets of satisfying initial states are shown in yellow). For linear dynamics and a particular choice of polytope-to-polytope controllers, the procedure is complete (i.e., guaranteed to terminate and to find the maximal set). The yellow region from (d) is the maximal set of satisfying initial states. Sample trajectories of the closed loop system are shown in d, where the initial states are marked by circles. The trajectories coincide in the last six steps before they reach the target region. (Example adapted from Belta et al. 2017)

Formal Methods for Controlling Dynamical Systems, Fig. 3 For the system described in Fig. 2, in addition to satisfying the temporal logic specification, the system is required to minimize a quadratic cost that penalizes the Euclidean distance from desired state and control trajectories, which are available to the system over a short finite-time horizon N . The reference trajectory is shown in green (satisfying in the left and middle and violating in the right), and the trajectory of the controlled system is shown

in red. Pairs of points on the reference and controlled trajectory corresponding to the same time are connected. The left and middle cases correspond to increasing values of the horizon N for the same reference trajectory. Note that, in the situation shown in the right, where the reference trajectory violates the correctness specification, the controller “tries to compromise” between correctness and optimality. (Example adapted from Belta et al. 2017)

added (possibly weighted by a constant) to the cost defined above, the optimization problem remains a MILP (MIQP). Adding robustness in the cost allows to compromise between correctness and optimality (see Fig. 4 and its caption.)

The main advantage of MIP-based methods is the seamless combination of correctness and optimality, with the added feature of robustness to satisfaction. Another advantage is scalability. Such methods produced results for systems with hundreds of state variables in seconds. The main limitation of such methods is that they are constrained to linear dynamics.

CBF-type methods address some of the limitations of the MIP-based methods. A pictorial representation of a CBF-based approach is shown in Fig. 5. In short, such methods work for a particular class of nonlinear control systems, called affine control systems, which is large enough to include many mechanical systems, such as unicycles, cars, etc., costs that are quadratic in controls, linear control constraints, and safety constraints expressed as set forward invariance. By dividing the time interval of interest into smaller time intervals, a nonlinear optimization problem can

be reduced to a set of quadratic programs (QP). Richer, temporal logic correctness constraints can also be incorporated in this framework.

Summary and Future Directions

While provably correct, automata-based approaches to formal synthesis of control strategies are computationally expensive. Current research that addresses this limitation is focused on identifying system properties that facilitate the construction of the abstraction (e.g., passivity, dissipativity) (Coogan and Arcak 2017) and compositional synthesis and assume guarantee-type approaches (Kim et al. 2017).

Optimization-based approaches based on mixed integer programming scale can quantify satisfaction and can compromise between correctness and optimality. However, they are restricted to linear dynamics. Optimization-based approaches based on control barrier functions and control Lyapunov functions can be used with nonlinear systems that are affine in controls. One of the main limitations of these types of approaches is that the optimization problems can

Formal Methods for Controlling Dynamical Systems,

Fig. 4 A planar discrete-time (integrator) linear system $x[t+1] = Ax[t] + Bu[t] + w[t]$ with state $x = (x_1, x_2)$, control u , $A = \begin{bmatrix} 1 & 0.5 \\ 0 & 0.8 \end{bmatrix}$, $B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$ is affected by noise w . The specification requires that x_1 oscillate between $2 \leq x_1 \leq 4$ and $-4 \leq x_1 \leq -2$, with each interval being visited at least once within any five consecutive time steps. The corresponding STL formula is $\mathbf{G}_{[0,\infty)}(\mathbf{F}_{[0,4]}((x_1 \geq 2) \wedge (x_1 \leq 4))) \wedge (\mathbf{F}_{[0,4]}((x_1 \geq -4) \wedge (x_1 \leq -2)))$. Here, $\mathbf{F}_{[t_1,t_2]}\psi$ requires that ψ is eventually satisfied within $[t_1, t_2]$, while $\mathbf{G}_{[t_1,t_2]}\psi$

means that ψ is true for all times in $[t_1, t_2]$. The control effort $\sum_{t=0}^{H-1} |u|^2$ is minimized in (a) and (b), while in (c) the “robust” version of the cost $\sum_{t=0}^{H-1} -M(\rho - |\rho|) + |u|^2$ is considered (H is a time horizon that is large enough to be able to decide the truth value of the formula). It can be seen that, if only the control effort is minimized, the resulting strategy is not robust to noise. If robustness is included in the cost, then the produced trajectory satisfies the specification even if noise is added to the system. (Example adapted from Sadraddini and Belta 2015)

easily become infeasible, especially when many constraints (state limitations, control constraints, CBF and CLF constraints) become active. One possible approach to this problem is to soften some constraints that are not critical, such as those induced by CLFs. Another possible

approach would be to use machine learning techniques to increase feasibility. For example, for a robot moving in an environment cluttered with obstacle, the configuration space can be sampled close to the obstacles, and the samples could be classifier depending on whether

Formal Methods for Controlling Dynamical Systems, Fig. 5 CBF-based approach to provably correct and optimal control synthesis: An affine control system is required to minimize a quadratic cost while converging to a desired final state and satisfying a safety specification expressed as the forward invariance of a set C and polyhedral control constraints U . Assuming that a CBF $B(x)$ can be constructed for C , then safety is guaranteed if the CBF constraint is satisfied. If a control Lyapunov function

(CLF) $V(x)$ can be constructed, then exponential convergence to the desired state is guaranteed if the CLF constraint is satisfied. By discretizing the time and keeping the state constant in each time interval, both constraints become linear in control, and the problem reduces to a set of QPs. L_f and L_g denote Lie derivatives along f and g , respectively. P is a positive definite matrix and c_3 and γ are positive constants

the corresponding QP is feasible or not. The (differentiable) classifier could be used as an extra CBF. Another active area of research is integrating correctness specifications given in rich, temporal logic specifications. Very recent results (Lindemann and Dimarogonas 2019) show that STL specifications can be enforced using CBF.

Frequency Domain System Identification

Johan Schoukens and Rik Pintelon
Department ELEC, Vrije Universiteit Brussel,
Brussels, Belgium

Abstract

In this chapter we give an introduction to frequency domain system identification. We start from the identification work loop in ► [System Identification: An Overview](#), Fig. 4, and we discuss the impact of selecting the time or frequency domain approach on each of the choices that are in this loop. Although there is a full theoretical equivalence between the time and frequency domain identification approach, it turns out that, from practical point of view, there can be a natural preference for one of both domains.

Keywords

Discrete and continuous time models · Experiment setup · Frequency and time domain identification · Plant and noise model

Introduction

System identification provides methods to build a mathematical model for a dynamical system starting from measured input and output signals (► [System Identification: An Overview](#); see the section “Models and System Identification”). Initially, the field was completely dominated by the time domain approach, and the frequency domain was used to interpret the results (Ljung

and Glover 1981). This picture changed in the nineteenth of the last century by the development of advanced frequency domain methods (Ljung 2006; Pintelon and Schoukens 2012), and nowadays it is widely accepted that there is a full theoretical equivalence between time and frequency domain system identification under some weak conditions (Agüero et al. 2009; Pintelon and Schoukens 2012). Dedicated toolboxes are available for both domains (Ljung 1988; Kollar 1994). This raises the question how to choose between time and frequency domain identification. Many times the choice between both approaches can be made based on the user's familiarity with one of two methods. However, for some problems it turns out that there is a natural preference for the time or the frequency domain. This contribution discusses the main issues that need to be considered when making this choice, and it provides additional insights to guide the reader to the best solutions for her/his problem.

In the identification work loop ► [System Identification: An Overview](#), Fig. 4, we need to address three important questions (Ljung 1999, Sect. 1.4; Söderström and Stoica 1989, Chap. 1; Pintelon and Schoukens 2012, Sect. 1.4) that directly interact with the choice between time and frequency domain system identification:

- What data are available? What data are needed? This discussion will influence the selection of the measurement setup, the model choice, and the design of the experiment.
- What kind of models will be used? We will mainly focus on the identification of discrete time and continuous time models, using exactly the same frequency domain tools.
- How will the model be matched to the data? This question boils down to the choice of a cost function that measures the distance between the data and the model. We will discuss the use of nonparametric weighting functions in the frequency domain.

In the next sections, we will address these and similar questions in more detail. First, we discuss

the measurement of the raw data. The choices that are made in this step will have a strong impact on many user aspects of the identification process. The frequency domain formulation will turn out to be a natural choice to propose a unified formulation of the system identification problem, including discrete and continuous time modeling. Next, a generalized frequency domain description of the system relation will be proposed. This model will be matched to the data, using a weighted least squares cost function, formulated in the frequency domain identification. This will allow for the use of nonparametric weighting functions, based on a nonparametric preprocessing of the data. Eventually, some remaining user aspects are discussed.

Data Collection

In this section, we discuss the measurement assumptions that are made when the raw data are collected. It will turn out that these will directly influence the natural choice of the models that are used to describe the continuous time physical systems.

Time Domain and Frequency Domain Measurements

The data can be collected either in the time or in the frequency domain, and we discuss briefly both options.

Time Domain Measurements

Most measurements are nowadays made in the time domain because very fast high-quality analog-to-digital convertors (ADC) became available at a low price. These allow us to sample and discretize the continuous time input and output signals and process these on a digital computer. Also the excitation signals are mostly generated from a discrete time sequence with a digital-to-analog convertor (DAC).

The continuous time input and output signals $u_c(t)$, $y_c(t)$ of the system to be modeled are measured at the sampling moments $t_k = kT_s$, with $T_s = 1/f_s$ the sampling period and

f_s the sampling frequency: $u(k) = u_c(kT_s)$, and $y(k) = y_c(kT_s)$. The discrete time signals $u(k), y(k)$, $k = 1, \dots, N$ are transformed to the frequency domain using the discrete Fourier transform (DFT) (► [Nonparametric Techniques in System Identification](#), Eq. 1), resulting in the DFT spectra $U(l), Y(l)$, at the frequencies $f_l = l \frac{f_s}{N}$. Making some abuse of notation, we will reuse the same symbols later in this text, to denote the Z-transform of the signals, for example, $Y(z)$ will also be used for the Z-transform of $y(k)$.

Frequency Domain Measurements

A major exception to this general trend toward time domain measurements are the (high-frequency) network analyzers that measure the transfer function of a system frequency by frequency, starting from the steady-state response to a sine excitation. The frequency is stepped over the frequency band of interest, resulting directly in a measured frequency response function at a user selected set of frequencies $\omega_k, k = 1, \dots, F$:

$$G(\omega_k).$$

From the identification point of view, we can easily fit the latter situation in the frequency domain identification framework, by putting

$$U(k) = 1, Y(k) = G(\omega_k).$$

For that reason we will focus completely on the time domain measurement approach in the remaining part of this contribution.

Zero-Order-Hold and Band-Limited Setup: Impact on the Model Choice

No information is available on how the continuous time signals $u_c(t), y_c(t)$ vary in between the measured samples $u(k), y(k)$. For that reason we need to make an assumption and make sure that the measurement setup is selected such that the intersample assumption is met. Two intersample assumptions are very popular (Schoukens et al. 1994; Pintelon and Schoukens 2012, pp. 498–512): the zero-order-hold (ZOH) and the band-limited assumption (BL). Both options are shown in Fig. 1 and discussed below. The choice of these assumptions does not only affect the measurement setup; it has also a strong impact on the selection between a continuous or a discrete time model choice.

Zero-Order Hold

The ZOH setup assumes that the excitation remains constant in between the samples. In practice, the model is identified between the discrete time reference signal in the memory

Frequency Domain System Identification, Fig. 1 Comparison of the ZOH and BL signal reconstruction of a discrete time sequence: (a) time domain: $\cdots$ BL, $-$ ZOH; (b) spectrum ZOH signal; (c) spectrum BL signal

of the generator and the sampled output. The intersample behavior is an intrinsic part of the model: if the intersample behavior changes, also the corresponding model will change. The ZOH assumption is very popular in digital control. In that case the sampling frequency f_s is commonly chosen 10 times larger than the frequency band of interest.

A discrete time model gives, in case of noise-free data, an exact description between the sampled input $u(k)$ and output $y(k)$ of the continuous time system:

$$y(k) = G(q, \theta)u(k)$$

in the time domain (► [System Identification: An Overview](#), Eq. 6). In this expression, q denotes the shift operator (time domain), and it is replaced by z in the z -domain description (transfer function description):

$$Y(z) = G(z, \theta)U(z).$$

Evaluating the transfer function at the unit circle by replacing $z = e^{i\omega}$ results in the frequency domain description of the system:

$$Y(e^{i\omega}) = G(e^{i\omega}, \theta)U(e^{i\omega})$$

(► [System Identification: An Overview](#), Eq. 34).

Band-Limited Setup

The BL setup assumes that above a given frequency $f_{\max} < f_s/2$, there is no power in the signals. The continuous time signals are filtered by well-tuned anti-alias filters (cutoff frequency $f_{\max} < f_s/2$), before they are sampled. Outside the digital control world, the BL setup is the standard choice for discrete time measurements. Without using anti-alias filters, large errors can be created due to aliasing effects: the high frequency ($f > f_s/2$) content of the measured signals is folded down in the frequency band of interest and act there as a disturbance. For that reason it is strongly advised to use always anti-alias filters in the measurement setup.

The exact relation between BL signals is described by a continuous time model, for

example, in the frequency domain:

$$Y(\omega) = G(\omega, \theta)U(\omega)$$

(Schoukens et al. 1994).

Combining Discrete Time Models and BL Data

It is also possible to identify a discrete time model between the BL data, at a cost of creating (very) small model errors (Schoukens et al. 1994). This is the standard setup that is used in digital signal procession applications like digital audio processing. The level of the model errors can be reduced by lowering the ratio $f_{\max}/f_s$ or by increasing the model order. In a properly designed setup, the discrete time model errors can be made very small, e.g., relative errors below 10^{-5} . In Table 1 an overview of the models corresponding to the experimental conditions is given.

Extracting Continuous Time Models from ZOH Data

Although the most robust and practical choice to identify a continuous time model is to start from BL data, it is also possible to extract a continuous time model under the ZOH setup. A first possibility is to assume that the ZOH assumption is perfectly met, which is a very hard assumption to realize in practice. In that case the continuous time model can be retrieved by a linear step invariant transformation of the discrete time model. A second possibility is to select a very high sample frequency with respect to the bandwidth of the system. In that case it is advantageous to describe the discrete time model using the delta operator (Goodwin 2010), and we have that the coefficients of the discrete time model converge to those of the continuous time model.

Models of Cascaded Systems

In some problems we want to build models for a cascade of two systems G_1, G_2 . It is well known that the overall transfer function G is given by the product $G(\omega) = G_1(\omega)G_2(\omega)$. This result holds also for models that are identified under the BL signal assumption: the model for the cascade

Frequency Domain System Identification, Table 1 Relations between the continuous time system $G(s)$ and the identified models as a function of the signal and model choices

	DT-model (Assuming ZOH-setup)	CT-model (Assuming BL-setup)
ZOH setup	Exact DT-model $G(z) = (1 - z^{-1}) Z \left\{ \frac{G(s)}{s} \right\}$ ‘standard conditions DT modelling’	Not studied
BL setup	Approximate DT model $\tilde{G}(z) \tilde{G}(z = e^{j\omega T_s}) \approx G(s = j\omega),$ $ \omega < \frac{\omega_s}{2}$ ‘digital signal processing field’	Exact CT-model $G(s)$ ‘standard conditions CT modelling’

F

will be the product of the models of the individual systems. However, the result does not hold under the ZOH assumption, because the intermediate signal between G_1, G_2 does not meet the ZOH assumption. For that reason, the ZOH model of a cascaded system is not obtained by cascading the ZOH models of the individual systems.

Experiment Design: Periodic or Random Excitations?

In general, arbitrary data can be used to identify a system as long as some basic requirements are respected (► [System Identification: An Overview](#), section on Experiment Design). Imposing periodic excitations can be an important restriction of the user’s freedom to design the experiment, but we will show in the next sections that it offers also major advantages at many steps in the identification work loop (► [System Identification: An Overview](#), Fig. 4).

With the availability of arbitrary wave form generators, it became possible to generate arbitrary periodic signals. The user should make two major choices during the design of the periodic excitation: the selection of the amplitude spectrum (How is the available power distributed over the frequency?) and the choice of the frequency resolution (What is the frequency step between two successive points of the measured FRF?) (Pintelon and Schoukens 2012, Sect. 5.3).

The amplitude spectrum is mainly set by the requirement that the excited frequency band should cover the frequency band of interest. A white noise excitation covers the full frequency

band, including those bands that are of no interest for the user. This is a waste of power and it should be avoided. Designing a good power spectrum for identification and control purposes is discussed in ► [Experiment Design and Identification for Control](#).

The frequency resolution $f_0 = 1/T$ is set by the inverse of the period of the signal. It should be small enough so that no important dynamics are missed, e.g., a very sharp mechanical resonance.

The reader should be aware that exactly the same choices have to be made during the design of nonperiodic excitations. If, for example, a random noise excitation is used, the frequency resolution is also restricted by the length of the experiment T_m and the corresponding frequency resolution is again $f_0 = 1/T_m$. The power spectrum of the noise excitation should be well shaped using a digital filter.

Nonparametric Preprocessing of the Data in the Frequency Domain

Before a parametric model is identified from the raw data, a lot of information can be gained, almost for free, by making a nonparametric analysis of the data. This can be done with very little user interaction. Some of these methods are explicitly linked to the periodic nature of the data, other methods apply also to random excitations.

Nonparametric Frequency Analysis of Periodic Data

By using simple DFT techniques, the following frequency domain information is extracted

from sampled time domain data $u(t), y(t), t = 1, \dots, N$ (Pintelon and Schoukens 2012):

- The signal information: $U(l), Y(l)$, the DFT spectra of the input and output, evaluated at the frequencies lf_0 , with $k = 1, 2, \dots, F$.
- Disturbing noise variance information: The full data record is split, so that each sub-record contains a single period. For each of these, the DFT spectrum is calculated. Since the signals are periodic, they do not vary from one period to the other, so that the observed variations can be attributed to the noise. By calculating the sample mean and variance over the periods at each frequency, a nonparametric noise analysis is available. The estimated variances $\hat{\sigma}_U^2(k), \hat{\sigma}_Y^2(k)$ measure the disturbing noise power spectrum at frequency f_k on the input and the output respectively. The covariance $\hat{\sigma}_{YU}^2(k)$ characterizes the linear relations between the noise on the input and the output.

This is very valuable information because, even before starting the parametric identification step, we get already full access to the quality of the raw data. As a consequence, there is also no interference between the plant model estimation and the noise analysis: plant model errors do not affect the estimated noise model. It is also important to realize that there is no user interaction requested to make this analysis and it follows directly from a simple DFT analysis of the raw data. These are two major advantages of using periodic excitations.

Nonlinear Analysis

Using well-designed periodic excitations, it is possible to detect the presence of nonlinear distortions during the nonparametric frequency step. The level of the nonlinear distortions at the output of the system is measured as a function of the frequency, and it is even possible to differentiate between even (e.g., x^2) and odd (e.g., x^3) distortions. While the first only act as disturbing noise in a linear modeling framework, the latter will also affect the linearized dynamics and can

change, for example, the pole positions of a system (Pintelon and Schoukens 2012, Sect. 4.3).

Noise and Data Reduction

By averaging the periodic signals over the successive periods, we get a first reduction of the noise. An additional noise reduction is possible when not all frequencies are excited. If a very wide frequency band has to be covered, a fine frequency resolution is needed at the low frequencies, whereas in the higher frequency bands, the resolution can be reduced. Signals with a logarithmic frequency distribution are used for that purpose. Eliminating the unexcited frequencies does not only reduce the noise, it also reduces significantly the amount of raw data to be processed. By combining different experiments that cover each a specific frequency band, it is possible to measure a system over multiple decades, e.g., electrical machines are measured from a few mHz to a few kHz.

In a similar way, it is also possible to focus the fit on the frequency band of interest by including only those frequencies in the parametric modeling step.

High-Quality Frequency Response Function Measurements

For periodic excitations, it is very simple to obtain high-quality measurements of the nonparametric frequency response function of the system. These results can be extended to random excitations at a cost of using more advanced algorithms that require more computation time (Pintelon and Schoukens, Chap. 7). This approach is discussed in detail in ► [Nonparametric Techniques in System Identification](#) (Eq. 1).

Generalized Frequency Domain Models

A very important step in the identification work loop is the choice of the model class (► [System Identification: An Overview](#), Fig. 4). Although most physical systems are continuous time, the models that we need might be either discrete time (e.g., digital control, computer simulations,

digital signal processing) or continuous time (e.g., physical interpretation of the model, analog control) (Ljung 1999, Sects. 2.1 and 4.3). A major advantage of the frequency domain is that both model classes are described by the same transfer function model. The only difference is the choice of the frequency variable. For continuous time models we operate in the Laplace domain, and the frequency variable is retrieved on the imaginary axis by putting $s = j\omega$. For discrete time systems we work on the unit circle that is described by the frequency variable $z = e^{j2\pi f/f_s}$. The application class can be even extended to include diffusion phenomena by putting $\Omega = \sqrt{j\omega}$ (Pintelon et al. 2005). From now on we will use the generalized frequency variable Ω , and depending on the selected domain, the proper substitution $j\omega$, $e^{j2\pi f/f_s}$, $\sqrt{j\omega}$ should be made. The unified discrete and continuous time description

$$Y(k) = G(\Omega_k, \theta)U(k).$$

illustrates also very nicely that in the frequency domain there is a strong similarity between discrete and continuous time system identification.

To apply this model to finite length measurements, it should be generalized to include the effect of the initial conditions (time domain) or the begin and end effects (called leakage in the frequency domain). See ► [Nonparametric Techniques in System Identification](#), “The Leakage Problem” section. The amazing result is that in the frequency domain, both effects are described

by exactly the same mathematical expression. This leads eventually to the following model in the frequency domain that is valid for periodic and arbitrary (nonperiodic) BL or ZOH excitations (Pintelon et al. 1997; McKelvey 2002; Pintelon and Schoukens 2012, Chap. 6):

$$Y(k) = G(\Omega, \theta)U(k) + T_G(\Omega, \theta)$$

which becomes for SISO (single-input-single-output) systems:

$$G(\Omega, \theta) = \frac{B(\Omega, \theta)}{A(\Omega, \theta)}, \text{ and } T_G(\Omega, \theta) = \frac{I(\Omega, \theta)}{A(\Omega, \theta)}.$$

A, B, I are all polynomials in Ω . The transient term $T_G(\Omega, \theta)$ models transient and leakage effects. It is most important for the reader to realize that this is an exact description for noise free data. Observe that it is very similar to the description in the time domain: $y(t) = G(q, \theta)u(t) + t_G(t, \theta)$. In that case the transient term $t_G(t, \theta)$ models the initial transient that is due to the initial conditions.

Parametric Identification

Once we have the data and the model available in the frequency domain, we define the following weighted least squares cost function to match the model to the data (Schoukens et al. 1997):

$$V(\theta) = \frac{1}{F} \sum_{k=1}^F \frac{|\hat{Y}(k) - G(\Omega_k, \theta)\hat{U}(k) - T_G(\Omega_k, \theta)|^2}{\hat{\sigma}_Y^2(k) + \hat{\sigma}_U^2(k)|G(\Omega_k, \theta)|^2 - 2\text{Re}(\hat{\sigma}_{YU}^2(k)G(\Omega_k, \theta))}.$$

The properties of this estimator are fully studied in Schoukens et al. (1999) and Pintelon and Schoukens (2012, Sect. 10.3), and it is shown that it is a consistent and almost efficient estimator under very mild conditions.

The formal link with the time domain cost function, as presented in ► [System Identification: An Overview](#), can be made by assuming that the

input is exactly known ($\hat{\sigma}_U^2(k) = 0$, $\hat{\sigma}_{YU}^2(k) = 0$), and replacing the nonparametric noise model on the output by a parametric model:

$$\hat{\sigma}_Y^2(k) = \lambda |H(\Omega_k, \theta)|^2.$$

These changes reduce the cost function, within a parameter independent constant λ to

$$V_F(\theta) = \frac{1}{F} \sum_{k=1}^F \frac{\left| \hat{Y}(k) - G(\Omega_k, \theta) U_0(k) - T_G(\Omega_k, \theta) \right|^2}{|H(\Omega_k, \theta)|^2},$$

which is exactly the same expression as Eq. 37 in [►System Identification: An Overview](#), provided that the frequencies Ω_k cover the full unit circle and the transient term T_G is omitted. The latter models the initial condition effects in the time domain. The expression shows the full equivalence with the classical discrete time domain formulation. If only a subsection of the full unit circle is used for the fit, the additional term $N \log \det \Lambda$ in [►System Identification: An Overview](#), Eq. 21 should be added to the cost function $V_F(\theta)$.

Additional User Aspects in Parametric Frequency Domain System Identification

In this section we highlight some additional user aspects that are affected by the choice for a time or frequency approach to system identification.

Nonparametric Noise Models

The use of a nonparametric noise model is a natural choice in the frequency domain. It is of course also possible to use the parametric noise model in the frequency domain formulation, but then we would lose two major advantages of the frequency domain formulation: (i) For periodic excitations, there is no interaction between the identification of the plant model and the nonparametric noise model. Plant model errors do not show up in the noise model. (ii) The availability of the nonparametric noise models eliminates the need for tuning the parametric noise model order, resulting in algorithms that are easier to use.

A disadvantage of using a nonparametric noise model is that we can no longer express that the noise model can share some dynamics with the plant model, for example, when the disturbance is an unobserved plant input.

It is also possible to use a nonparametric noise model in the time domain. This leads to a

Toeplitz weighting matrix, and the fast numerical algorithms that are used to deal with these make use internally of FFT (fast Fourier transform) algorithms which brings us back to the frequency domain representation of the data.

Stable and Unstable Plant Models

In the frequency domain formulation, there is no special precaution needed to deal with unstable models, so that we can tolerate these models without any problem. There are multiple reasons why this can be advantageous. The most obvious one is the identification of an unstable system, operating in a stabilizing closed loop. It can also happen that the intermediate models that are obtained during the optimization process are unstable. Imposing stability at each iteration can be too restrictive, resulting in estimates that are trapped in a local minimum. A last significant advantage is the possibility to split the identification problem (extract a model from the noisy data) and the approximation problem (approximate the unstable model by a stable one). This allows us to use in each step a cost function that is optimal for that step: maximum noise reduction in the first step, followed by a user-defined approximation criterion in the second step.

Model Selection and Validation

An important step in the system identification procedure is the tuning of the model complexity, followed by the evaluation of the model quality on a fresh data set. The availability of a nonparametric noise model and a high-quality frequency response function measurement simplifies these steps significantly:

Absolute Interpretation of the Cost Function:

Impact on Model Selection and Validation

The weighted least squares cost function, using the nonparametric noise weighting, is a normalized function. Its expected value equals

$E\{V(\hat{\theta})\} = (F - n_{\theta}/2)/F$, with n_{θ} the number of free parameters in the model and F the number of frequency points. A cost function that is far too large points to remaining model errors. Unmodeled dynamics result in correlated residuals (difference between the measured and the modeled FRF): the user should increase the model order to capture these dynamics in the linear model. A cost function that is far too large, while the residuals are white, points to the presence of nonlinear distortions: the best linear approximation is identified, but the user should be aware that this approximation is conditioned on the actual excitation signal. A cost function that is far too low points to an error in the preprocessing of the data, resulting in a bad noise model.

Missing Resonances

Some systems are lightly damped, resulting in a resonant behavior, for example, a vibrating mechanical structure. By comparing the parametric transfer function model with the nonparametric FRF measurements, it becomes clearly visible if a resonance is missed in the model. This can be either due to a too simple model structure (the model order should be increased), or it can appear because the model is trapped in a local minimum. In the latter case, better numerical optimization and initialization procedures should be looked for.

Identification in the Presence of Noise on the Input and Output Measurements

Within the band-limited measurement setup, both the input and the output have to be measured. This leads in general to an identification framework where both the input and the output are disturbed by noise. Such problems are studied in the errors-in-variables (EIV) framework (Soderstrom 2012). A special case is the identification of a system that is captured in a feedback loop. In that case we have that the noisy output measurements are fed back to the input of the system which creates a dependency between the input and output disturbance. We discuss both situations briefly below.

Errors-in-Variables Framework

The major difficulty of the EIV framework is the simultaneous identification of the plant model describing the input-output relations, the noise models that describe the input and the output noise disturbances, and the signal model describing the coloring of the excitation (Soderstrom 2012). Advanced identification methods are developed, but today it is still necessary to impose strong restrictions on the noise models, e.g., correlations between input and output noise disturbances are not allowed. The periodic frequency domain approach encapsulates the general EIV, including mutually correlated colored input-output noise. Again, a full nonparametric noise model is obtained in the preprocessing step. This reduces the complexity of the EIV problem to that of a classical weighted least squares identification problem which makes a huge difference in practice (Söderström et al. 2010; Pintelon and Schoukens 2012).

Identification in a Feedback Loop

Identification under feedback conditions can be solved in the time domain prediction error method (Ljung 1999, Sect. 13.4; Söderström and Stoica 1989, Chap. 10). This leads to consistent estimates, provided that the exact plant and noise model structure and order is retrieved. In the periodic frequency domain approach, a nonparametric noise model is extracted (variances input and output noise, and covariance between input and output noise) in the preprocessing step, without any user interaction. Next, these are used as a weighting in the weighted least squares cost function which leads to consistent estimates provided that the plant model is flexible enough to capture the true plant transfer function (Pintelon and Schoukens 2012, Sect. 9.18).

Summary and Future Directions

Theoretically, there is a full equivalence between the time and frequency domain formulation of the system identification problem. In many practical situations the user can make a free choice between both approaches, based on

nontechnical arguments like familiarity with one of both domains. However, some problems can be easier formulated in the frequency domain. Identification of continuous time models is not more involved than retrieving a discrete time model. The frequency domain formulation is also the natural choice to use nonparametric noise models. This eliminates the request to select a specific noise model structure and order, although this might be a drawback for experienced users who can take advantage of a clever choice of this structure. The advantages that are directly linked to periodic excitation signals can be explored most naturally in the frequency domain: the noise model is available for free, EIV identification is not more involved than the output error identification problem, and identification under feedback conditions does not differ from open-loop identification. Nonstationary effects are an example of a problem that will be easier detected in the time domain. In general, we advise the reader to take the best of both approaches and to swap from one domain to the other whenever it gives some advantage to do so. In the future, it will be necessary to extend the framework to include a characterization of nonlinear and time-varying effects.

Recommended Reading

We recommend the reader the books of Ljung (1999) and Söderström and Stoica (1989) for a systematic study of time domain system identification. The book of Pintelon and Schoukens (2012) gives a comprehensive introduction to frequency domain identification. An extended discussion of the basic choices (intersample behavior, measurement setup) is given in Chap. 13 of

Pintelon and Schoukens (2012) or in Schoukens et al. (1994). The other references in this list highlight some of the technical aspects that were discussed in this text.

Abstract

A major advantage of using frequency response is the ease with which experimental information can be used for design purposes. Raw measurements of the output amplitude and phase of a plant undergoing a sinusoidal input excitation are sufficient to design a suitable feedback control. No intermediate processing of the data (such as finding poles and zeros or determining system matrices) is required to arrive at the system model. The wide availability of computational and system identification software tools has rendered this advantage less important now than it was years ago; however, for relatively simple systems, frequency response is often still the most cost-effective design method. The method is most effective for systems that are stable in open loop but can also be applied to unstable systems. Yet another advantage is that it is the easiest method to use for designing dynamic compensation as seen in the **Cross-Reference** article: [1] ▶ “Classical Frequency-Domain Design Methods”.

Introduction

A very common way to use the exponential response of linear time-invariant systems (LTIs) is in finding the **frequency response**, or response to a sinusoid. First we express the sinusoid as a sum of two exponential expressions (Euler's relation):

$$A \cos(\omega t) = \frac{A}{2} (e^{j\omega t} + e^{-j\omega t}). \quad (1)$$

Suppose we have an LTI system with input u and output y , where we define the transfer function

$$G(s) = \frac{Y(s)}{U(s)}. \quad (2)$$

If we let $s = j\omega$ in $G(s)$, then the response to $u(t) = e^{j\omega t}$ is $y(t) = G(j\omega)e^{j\omega t}$; similarly, the response to $u(t) = e^{-j\omega t}$ is $G(-j\omega)e^{-j\omega t}$. By superposition, the response to the sum of these two exponentials, which make up the cosine signal, is the sum of the responses:

$$y(t) = \frac{A}{2} [G(j\omega)e^{j\omega t} + G(-j\omega)e^{-j\omega t}]. \quad (3)$$

The transfer function $G(j\omega)$ is a complex number that can be represented in polar form or in magnitude-and-phase form as $G(j\omega) = M(\omega)e^{j\varphi(\omega)}$ or simply $G = Me^{j\varphi}$. With this substitution, Eq. (3) becomes for a specific input frequency $\omega = \omega_o$

$$\begin{aligned} y(t) &= \frac{A}{2} M \left(e^{j(\omega_o t + \varphi)} + e^{-j(\omega_o t + \varphi)} \right), \\ &= AM \cos(\omega t + \varphi), \\ M &= |G(j\omega)| = |G(s)|_{s=j\omega_o} \end{aligned} \quad (4)$$

$$= \sqrt{\{\operatorname{Re}[G(j\omega_o)]\}^2 + \{\operatorname{Im}[G(j\omega_o)]\}^2},$$

$$\varphi = \angle G(j\omega) = \tan^{-1} \left[\frac{\operatorname{Im}[G(j\omega_o)]}{\operatorname{Re}[G(j\omega_o)]} \right]. \quad (5)$$

This means that if an LTI system represented by the transfer function $G(s)$ has a sinusoidal input with magnitude A , the output will be sinusoidal at the *same* frequency with magnitude AM and will be shifted in phase by the angle φ . M is usually referred to as the **amplitude ratio** or **magnitude**, and φ is referred to as the **phase**, and they are both functions of the input frequency, ω . The frequency response can be measured experimentally quite easily in the laboratory by driving the system with a known sinusoidal input, letting the transient response die, and measuring the steady-state amplitude and phase of the system's output as shown in Fig. 1. The input frequency is set to sufficiently many values so that curves such as the one in Fig. 2 are obtained. Bode suggested that we plot $\log |M|$ vs $\log \omega$ and $\varphi(\omega)$ vs $\log \omega$ to best show the essential features of $G(j\omega)$. Hence such plots are referred to as Bode plots. Bode plotting techniques are discussed in Franklin et al. (2019).

We are interested in analyzing the frequency response not only because it will help us understand how a system responds to a sinusoidal input but also because evaluating $G(s)$ with s taking on values along the $j\omega$ axis will prove to be very useful in determining the stability of a closed-loop system. Evaluating $G(j\omega)$ provides

information that allows us to determine closed-loop stability from the open-loop $G(s)$.

For the standard second-order system

$$G(s) = \frac{1}{(s/\omega_n)^2 + 2\zeta(s/\omega_n) + 1}, \quad (6)$$

the Bode plot is shown in Fig. 3 for various values of ζ .

A natural specification for system performance in terms of frequency response is the **bandwidth**, defined to be the maximum frequency at which the output of a system will track an input sinusoid in a satisfactory manner. By convention, for the system shown in Fig. 4 with a sinusoidal input R , the bandwidth is the frequency of R at which the output Y is attenuated to a factor of 0.707 times the input (If the output is a voltage across a $1\text{-}\Omega$ resistor, the power is v^2 and when $|v| = 0.707$, the power is reduced by a factor of 2. By convention, this is called the half-power point.). Figure 5 depicts the idea graphically for the frequency response of the *closed-loop* transfer function

$$\frac{Y(s)}{R(s)} \triangleq T(s) = \frac{KG(s)}{1 + KG(s)}. \quad (7)$$

The plot is typical of most closed-loop systems in that (1) the output follows the input ($|T| \cong 1$) at the lower excitation frequencies and (2) the output ceases to follow the input ($|T| < 1$) at

Frequency-Response and Frequency-Domain Models, Fig. 1

the higher excitation frequencies. The maximum value of the frequency-response magnitude is referred to as the **resonant peak** M_r .

Bandwidth is a measure of speed of response and is therefore similar to time-domain measures such as rise time and peak time or the s -plane measure of dominant root(s) natural frequency. In fact, if the $K G(s)$ in Fig. 4 is such that the closed-loop response is given by Fig. 3a, we can see that the bandwidth will equal the natural frequency of the closed-loop root (i.e., $\omega_{BW} = \omega_n$ for a closed-loop damping ratio of $\zeta = 0.7$). For other damping ratios, the bandwidth is approximately equal to the natural frequency of the closed-loop roots, with an error typically less than a factor of 2.

For a second-order system, the time responses are functions of the pole-location parameters ζ and ω_n . If we consider the curve for $\zeta = 0.5$ to be an average, the rise time (t_r) from $y = 0.1$ to $y = 0.9$ is approximately $\omega_n t_r = 1.8$. Thus we can say that

$$t_r \approx \frac{1.8}{\omega_n}. \quad (8)$$

Although this relationship could be embellished by including the effect of the damping ratio, it is important to keep in mind how Eq. (8) is

typically used. It is accurate only for a second-order system with no zeros; for all other systems, it is a rough approximation to the relationship between t_r and ω_n . Most systems being analyzed for control systems design are more complicated than the pure second-order system, so designers use Eq. (8) with the knowledge that it is a rough approximation only. For a second-order system, the bandwidth is inversely proportional to the rise time, t_r . Hence we are able to link the time and frequency domain quantities in this way.

The definition of the bandwidth stated here is meaningful for systems that have a low-pass filter behavior, as is the case for any physical control system. In other applications the bandwidth may be defined differently. Also, if the ideal model of the system does not have a high-frequency roll-off (e.g., if it has an equal number of poles and zeros), the bandwidth is infinite; however, this does not occur in nature as physical systems don't respond well at infinite frequencies.

In many cases, the designer's primary concern is the error in the system due to disturbances rather than the ability to track an input. For error analysis, we are more interested in the sensitivity function, $S(s) = 1 - T(s)$, rather than $T(s)$. In a feedback control system, as in Fig. 4, the

Frequency-Response and Frequency-Domain Models, Fig. 3 Frequency responses of standard second-order systems (a) magnitude, (b) phase. (Source: Franklin, Pow-

ell, Emami-Naeini, Feedback Control of Dynamic Systems, 8th Ed., © 2019, p-338, Reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ)

Frequency-Response and Frequency-Domain Models, Fig. 4 Unity feedback control system

sensitivity can be interpreted as either the error response to a reference input or the system response to an output disturbance:

$$S(s) = \frac{E(s)}{R(s)} = \frac{Y(s)}{Y_d(s)} = \frac{1}{1 + KG(s)}.$$

For most open-loop systems with high gain at low frequencies, $S(s)$ for a disturbance input has very low values at low frequencies, indicating an ability to attenuate low-frequency disturbances. The response to the input or disturbance grows as the frequency of the input or disturbance approaches ω_{DRB} . The **disturbance rejection bandwidth** ω_{DRB} characterizes the speed of the recovery from a disturbance, describing the frequency where the response to a disturbance has been reduced to 0.707 of the input disturbance, defined by Fig. 5. As such, the time to recover from a disturbance is inversely proportional to ω_{DRB} . Considering that $T(s) + S(s) = 1$, disturbances are attenuated so that $S(s) \rightarrow 0$ when the output tracks the input $T(s) \rightarrow 1$, as illustrated in Fig. 5. Therefore, an increase in bandwidth also increases the disturbance rejection bandwidth and typically $\omega_{DRB} < \omega_{BW}$. The maximum value of $S(s)$ is referred to as the disturbance rejection peak, M_d , which represents the maximum possible overshoot during a recovery from a disturbance.

For analysis of either $T(s)$ or $S(s)$, it is typical to plot their response versus the frequency of the input as shown in Fig. 5. Frequency response for control system design can either be evaluated using the computer, or it can be quickly sketched for simple systems using the efficient methods described in Franklin et al. (2019). The methods described next are also useful to expedite the

design process as well as to perform sanity checks on the computer output.

Neutral Stability: Gain and Phase Margins

In the early days of electronic communications, most instruments were judged in terms of their frequency response. It is therefore natural that when the feedback amplifier was introduced, techniques to determine stability in the presence of feedback were based on this response.

Suppose the closed-loop transfer function of a system is known. We can determine the stability of a system by simply inspecting the denominator in factored form (because the factors give the system roots directly) to observe whether the real parts are positive or negative. However, the closed-loop transfer function is usually not known; in fact, the whole purpose behind understanding the root-locus technique (see Franklin et al. 2019) is to be able to find the factors of the denominator in the closed-loop transfer function, given only the open-loop transfer function. Another way to determine closed-loop stability is to evaluate the frequency response of the *open-loop* transfer function $KG(j\omega)$ and then perform a test on that response. Note that this method also does not require factoring the denominator of the closed-loop transfer function. In this section we will explain the principles of this method.

Suppose we have a system defined by Fig. 6a and whose root locus behaves as shown in Fig. 6b; that is, instability results if K is larger than 2. The neutrally stable points lie on the imaginary axis – that is, where $K = 2$ and $s = j1.0$. Furthermore, all points on the root locus have the property that

$$|KG(s)| = 1 \quad \text{and} \quad \angle G(s) = -180^\circ.$$

At the point of neutral stability, we see that these root-locus conditions hold for $s = j\omega$, so

$$|KG(j\omega)| = 1 \quad \text{and} \quad \angle G(j\omega) = -180^\circ. \quad (9)$$

Frequency-Response and Frequency-Domain Models, Fig. 5 Definitions of bandwidth and disturbance rejection bandwidth, resonant peak, and disturbance peak. ($T(s)$ is blue, $S(s)$ is red)

Frequency-Response and Frequency-Domain Models, Fig. 6 Stability example: (a) system definition; (b) root locus. (Source: Franklin, Powell, Emami-Naeini,

Feedback Control of Dynamic Systems, 8th Ed., © 2019, p-355, Reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ)

Thus a Bode plot of a system that is neutrally stable (i.e., with K defined such that a closed-loop root falls on the imaginary axis) will satisfy the conditions of Eq. (9). Figure 7 shows the frequency response for the system whose root locus is plotted in Fig. 6 for various values of K . The magnitude response corresponding to $K = 2$ passes through 1 at the same frequency ($\omega = 1$ rad/sec) at which the phase passes through -180° , as predicted by Eq. (9).

Having determined the point of neutral stability, we turn to a key question: Does increasing the gain increase or decrease the system's stability? We can see from the root locus in Fig. 6b that any value of K less than the value at the neutrally stable point will result in a stable system. At the frequency ω where the phase $\angle G(j\omega) = -180^\circ$ ($\omega = 1$ rad/sec), the magnitude $|KG(j\omega)| < 1.0$ for stable values of K and > 1 for unstable values of K . Therefore, we have the following

Frequency-Response and Frequency-Domain Models, Fig. 7 Frequency-response magnitude and phase for the system in Fig. 6. (Source: Franklin, Powell, Emami-Naeini, *Feedback Control of Dynamic Systems*, 8th Ed., © 2019, p-356, Reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ)

trial stability condition, based on the character of the open-loop frequency response:

$$|KG(j\omega)| < 1 \quad \text{at} \quad \angle G(j\omega) = -180^\circ. \quad (10)$$

This stability criterion holds for all systems for which increasing gain leads to instability and $|KG(j\omega)|$ crosses the magnitude ($=1$) once, the most common situation. However, there are systems for which an increasing gain can lead from instability to stability; in this case, the stability condition is

$$|KG(j\omega)| > 1 \quad \text{at} \quad \angle G(j\omega) = -180^\circ. \quad (11)$$

Based on the above ideas, we can now define the robustness metrics gain and phase margins:

Phase Margin Suppose at ω_1 , $|G(j\omega_1)| = \frac{1}{K}$. How much more *phase* could the system tolerate (as a time delay, perhaps) before reaching the stability boundary? The answer to this question follows from Eq. (9), i.e., the phase margin (PM) is defined as

$$\text{PM} = \angle G(j\omega_1) - (-180^\circ). \quad (12)$$

Gain Margin Suppose at ω_2 , $\angle G(j\omega_2) = -180^\circ$. How much more *gain* could the system tolerate (as an amplifier, perhaps) before reaching the stability boundary? The answer to this question follows from Eq. (10), i.e., the gain margin (GM) is defined as

$$\text{GM} = \frac{1}{K|G(j\omega_2)|}. \quad (13)$$

There are also rare cases when $|KG(j\omega)|$ crosses magnitude ($=1$) more than once or where an increasing gain leads to instability. A rigorous way to resolve these situations is to use the Nyquist stability criterion as discussed in Franklin et al. (2019).

Closed-Loop Frequency Response

The closed-loop bandwidth was defined above. The natural frequency is typically within a factor of two of the bandwidth for a second-order system. We can help establish a more exact correspondence by making a few observations. Consider a system in which $|KG(j\omega)|$ shows the typical behavior

$$\begin{aligned} |KG(j\omega)| &\gg 1 \quad \text{for} \quad \omega \ll \omega_c, \\ |KG(j\omega)| &\ll 1 \quad \text{for} \quad \omega \gg \omega_c, \end{aligned}$$

where ω_c is the crossover frequency where $|G(j\omega)| = 1$. The closed-loop frequency-response magnitude is approximated by

Frequency-Response and Frequency-Domain Models, Fig. 8 Closed-loop bandwidth with respect to PM. (Source: Franklin, Powell, Emami-Naeini, Feedback Con-

trol of Dynamic Systems, 8th Ed., © 2019, p-386, Reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ)

$$|T(j\omega)| = \left| \frac{KG(j\omega)}{1 + KG(j\omega)} \right| \cong \begin{cases} 1, & \omega \ll \omega_c, \\ |KG|, & \omega \gg \omega_c. \end{cases} \quad (14)$$

In the vicinity of crossover, where $|KG(j\omega)| = 1$, $|T(j\omega)|$ depends heavily on the PM. A PM of 90° means that $\angle G(j\omega_c) = -90^\circ$, and therefore $|T(j\omega_c)| = 0.707$. On the other hand, PM = 45° yields $|T(j\omega_c)| = 1.31$.

The exact evaluation of Eq. (14) was used to generate the curves of $|T(j\omega)|$ in Fig. 8. It shows that the bandwidth for smaller values of PM is typically somewhat greater than ω_c , though usually it is less than $2\omega_c$; thus

$$\omega_c \leq \omega_{BW} \leq 2\omega_c. \quad (15)$$

Another specification related to the closed-loop frequency response is the resonant-peak magnitude M_r , defined in Fig. 5. For linear systems, M_r is generally related to the damping of the system. In practice, M_r is rarely used; most designers prefer to use the PM to specify the damping of a system, because the imperfections that make systems nonlinear or cause delays usually erode the phase more significantly than the magnitude.

It is also important in the design to achieve certain error characteristics, and these are often evaluated as a function of the input or disturbance

frequency. In some cases, the primary function of the control system is to regulate the output to a certain constant value in the presence of disturbances. For these situations, the key item of interest for the design would be the closed-loop frequency response of the error with respect to disturbance inputs and associated disturbance rejection bandwidth ω_{DRB} as well as the disturbance rejection peak M_d defined in Fig. 5.

Summary and Future Directions

The frequency response methods are the most popular because they easily account for model uncertainty and can be measured in the laboratory. A wide range of information about the system can be displayed in a Bode plot. The dynamic compensation can be carried out directly from the Bode plot. Extension of the ideas to multivariable systems has been done via singular value plots. Extension to nonlinear systems is still the subject of current research.

Fuel Cell Vehicle Optimization and Control

Miriam A. Figueroa-Santos and Anna G. Stefanopoulou
University of Michigan, Ann Arbor, MI, USA

Abstract

Fuel cell (FC) systems with onboard hydrogen storage offer long-range, fast refueling, and high power capability. These attributes make FC vehicles (FCVs) the best option for shared mobility and fleet vehicles with high utilization. A FC system consists of the stack, which performs the electrical conversion of hydrogen to electricity, the balance of plant (BOP) components including pumps and blowers which are responsible for supplying reactants (hydrogen and air) at the correct rates, humidification hardware, and thermal management. FCVs are typically hybridized with a battery to gain the regenerative energy and to improve the system durability by reducing the (a) transient and high current spikes, (b) idling at high open circuit potential, and (c) the number of startup and shutdown cycles. At the vehicle level, satisfying driver's torque/power demand is achieved by choosing the power split between the fuel cell and

battery. Additional improvements in fuel consumption can be achieved through preview or simultaneous optimization of vehicle speed and power split to regulate battery state of charge and fuel cell thermal management. In this entry, different optimal control strategies are reviewed and compared.

Introduction

Alternatives to the traditional internal combustion engine (ICE) are required to decarbonize the transportation, which accounts for almost 30% of all greenhouse gas emissions in the USA (Tanc et al. 2019) and nearly 20% in the rest of the world. Fuel cell electric vehicles (FCVs) are examples of the alternative to internal combustion engine vehicles (ICE) that are predominantly powered by fossil fuel. Fuel cell vehicles are mainly driven by fuel cells which convert chemical energy contained in hydrogen into electricity, providing a hybrid solution that combines the advantages of internal combustion engines and batteries (O'Hayre et al. 2016). Widespread adoption of FCVs is limited by a lack of hydrogen distribution and refueling infrastructure and high technology cost. Furthermore, the low volumetric energy density of compressed hydrogen storage onboard the vehicle limits the range to approximately 500 miles (Salahuddin et al. 2018). The main limiting factor in hydrogen production via hydrolysis of water is the amount of electricity required. If all petrol cars in the USA were replaced by fuel cell vehicles, an estimated 1.4–2.1 TW would be required to produce the needed hydrogen. This is far greater than the current total US electricity generating capacity of 1.2 TW (Chapman et al. 2019).

The current state of the art for light-duty fuel cell vehicles is the Toyota Mirai, Honda Clarity, and Hyundai Nexa. They have a range of 350 miles and can be refueled in 3–5 min (James 2020). A popular alternative vehicle con-

Fuel Cell Vehicle Optimization and Control, Fig. 1

Fuel cell vehicle (FCV) in the transportation sector. (Figure adapted from McK 2017.) Circle size represents the relative annual energy consumption of this vehicle type

figuration that will rely on renewable electric energy generation is the battery electric vehicle (BEV). Examples of the state of the art for BEVs are currently the Tesla Model 3 and S, Nissan Leaf, among others, which have a range of around 107–315 miles and recharge in 60–75 min. The BEVs' limitation compared to FCVs is their longer charging time and shorter mileage range, but they have lower cost, and their fuel infrastructure has been well established compared to the FCVs (Salahuddin et al. 2018). As Fig. 1 summarizes, most of the small cars will be BEVs, except robotic or autonomous vehicles that can and should operate with much higher utilization to become cost-effective, requiring multiple fast refueling events per day (James 2020). Applications such as shared-services, taxis, and buses, among others, can benefit by using fuel cell vehicles. Medium-duty vehicles (MDV) that operate continuously and in a fleet configuration with depot refueling would also benefit from transitioning to FC powertrains.

While fuel cell light-duty vehicles (LDVs) are commercially produced (though not widespread success), the development of heavy-duty fuel cell vehicles in long-haul trucks is accelerating. The US Department of Energy (DOE) in their efforts to implement FCVs determined a target of \$60/kW, a power density of 1.7 kWh/L, and a durability target of 30,000 h for heavy-duty vehicles (James 2020). They have expanded the focus towards heavy-duty applications due to

the stringent durability requirements compared to light-duty vehicle applications.

The durability and cost of the fuel cell system can be improved through optimization of the balance of plant (BOP) components such as air compressors, fuel processors, sensors, and water and heat management that affect fuel cell's performance. Great progress has been made toward achieving the Department of Energy's (DOEs) targets for reduction in stack component cost, including reducing the Pt in the catalyst. However, this attention has not been directed toward the BOP components, which is projected to reach 60% of the total cost by 2025 (James et al. 2018). Therefore, optimal control of the power split and the pumps, fans, and blowers would enable component downsizing and system simplification but may require careful coordination to protect the fuel cell from overheating or reactant starvation. This is important since degradation and hybridization affect the total cost of ownership (Lü et al. 2020).

Fuel cells are combined with another energy source as shown in Fig. 2 to meet stringent vehicle cold startup and transient response requirements and improve system durability (Liv 2011). Fuel cell and supercapacitor configurations for FCVs were investigated due to the high power density, fast transient response, longer life cycle, and high-frequency rate of charging and discharging (Hannan et al. 2014). A combination of fuel cell, battery, and supercapacitor has also

Fuel Cell Vehicle Optimization and Control, Fig. 2

Example of an automotive fuel cell system and its balance of plant (BOP) comprised of hydrogen and air paths and cooling and humidification systems based on the Toyota Mirai (Arg 2018) and (Pukrushpan et al. 2002)

been proposed at a very high cost to take advantage of both good qualities of the two energy sources. After determining the correct energy source for the FCV, a control strategy that minimizes the hydrogen consumption while ensuring highly efficient operation of the FCV and longevity of the energy sources needs to be determined.

Fuel Cell Vehicle System

An example of a fuel cell vehicle powertrain with the balance of plant is shown in Fig. 2 highlighting at the top the power splitting and energy management between a battery and the fuel cell. The dynamic response of the fuel cell and its ability to follow the load required to power a vehicle depend on managing the air and hydrogen paths that supply the reactants within the BOP. Textbook material with publicly available software to simulate the air and hydrogen path, along with the membrane humidity and temperature, can be found in Pukrushpan et al. (2002). The primary goal of the BOP is to avoid starvation in the cathode and anode that lead to fuel cell degradation (Daud et al. 2017). Combination of fuel cell to other energy sources (such as batteries) can provide load leveling and allows the system

to operate at lower cathode stoichiometric ratios (lower reactant flows), thus reducing the parasitic losses associated with the air compressor (Suhn and Stefanopoulou 2005). Although the air and hydrogen paths have been addressed extensively in the past, the integration of cooling, thermal, and humidification to maintain optimal membrane hydration and avoid flooding even during startup, shutdown, and storage periods across a wide range of environmental conditions is still the frontier in the control and optimization field.

The problem of how much power is required from the fuel cell and the battery also arises. The power split has to maintain efficient operation of its components for driving from point A to point B. The load profile as shown in Fig. 2 is converted into electrical power through the motor (P_{load}). Then, the power split of the battery power and fuel cell for an FCV is determined by: $P_{fc,net} = P_{load} - P_e$ where P_e is the power required by other onboard energy sources such as batteries and $P_{fc,net}$ is the fuel cell's net stack power. A schematic of how the power flow occurs in an FCV is shown in Fig. 2. Further terms can be added to this power split rule, such as DC/DC converter power, depending on the fuel cell vehicle configuration and components. The battery power is given by: $P_b = n_s n_p I_b V_t$ where n_p is the number of battery cells in parallel in

Fuel Cell Vehicle Optimization and Control, Fig. 3 Impact of the fuel cell temperature, relative humidity, and operating pressure on fuel cell polarization curve

a module, n_s is the number of battery modules in series for forming a stack, I_b is the battery current, and V_t is the terminal voltage of a battery cell.

The power required from the fuel cell is obtained through a fuel cell current demand (input) and a voltage V_{fc} (output) on each cell in a fuel cell stack. As shown in Fig. 3, the fuel cell voltage decreases as the current drawn from the fuel cell increases and depends in a nonlinear way on cell temperature humidity and pressure. The total voltage of the fuel cell stack is then given as $V_{st} = n_{fc} V_{fc}$, where V_{st} is the fuel cell stack voltage and n_{fc} is the number of fuel cells in series in a fuel cell stack. The fuel cell stack power is given as $P_{fc} = n_{fc} V_{fc} I_{fc}$, where P_{fc} is the fuel cell stack power and I_{fc} is the fuel cell current and is the same for all cells if they are all connected in series.

The fuel cell efficiency is calculated as $\eta = \frac{P_{fc,net}}{E_{(H_2)}}$, where $P_{fc,net} = P_{fc} - P_{aux}$ is the net power of the fuel cell stack, P_{aux} is the power for the auxiliary components managing the BOP with $E_{(H_2)} = \frac{(\Delta H I_{fc})}{nF}$ being the energy value of hydrogen consumed, $\Delta H = 285.8 \frac{kJ}{mol}$ is the hydrogen higher heating value, $F = 96,485 \frac{C}{mol}$ is the Faraday constant, and $n = 2$ is the number of moles of hydrogen. The fuel cell efficiency

increases until the maximum value of 55–60% in the low to medium range of fuel cell power (typically near 20% of peak power). Then it drops on the high power region of fuel cell operation. The polarization losses shaping the fuel cell voltage response shown in Fig. 3 are the fundamental reason behind the FC peak efficiency at approximately 20% of peak power. Control techniques to maintain the FC system operation automatically around that optimum have been investigated in the past and include full FC system optimization or FC pack efficiency peak-finding via extremum seeking.

Fuel Cell Operation

The FC performance is described by a voltage versus current (or current density) relationship called polarization and shown in Fig. 3. From the polarization curve expression, it is evident that pressure, temperature, and relative humidity will affect the fuel cell's performance. In Fig. 3, simulated polarization curves at different temperatures are shown for a fuel cell. It can be appreciated that from 65 to 80 °C, the fuel cell's voltage on the polarization curve increases, which means the fuel cell will operate at a higher efficiency. From 85 °C and onward, dehydration occurs within the fuel cell. Consequently, a decrease in voltage is

produced in the polarization curve. At operation lower than 60 °C, water vapor condensation could occur, and flooding in the fuel cell is probable also, causing stack loss performance (Li et al. 2012) similar to the ones at 85 °C. Therefore, the fuel cell requires a management system to maintain the fuel cell within the operating temperature range (60–80 °C), pressure, and humidity which is called the balance of plant and is discussed in the next section.

Balance of Plant (BOP)

The balance of plant (BOP) components are responsible for cooling the fuel cell stack, providing enough reactants, and allowing the reactants' humidification before entering the fuel cell stack. BOP also allows adequate recirculation for hydrogen and water to allow fuel cell operation efficiently. The balance of plant (BOP) components usually consist of a compressor for the air delivery system and a pump/heat-exchanger/fan for the cooling system. They also include a pump for hydrogen recirculation and water pumps or humidifiers for humidification. The BOP components for liquid-cooled stacks are shown in Fig. 2 and denoted by the red lines. The combination of the BOP with the fuel cell is known as the fuel cell system.

The reactants need to be controlled to improve the performance of the fuel cell. The hydrogen (provided by pump) and air (provided by compressor or fan) need to be maintained at a certain stoichiometric ratio to ensure the efficient performance of the fuel cell. High hydrogen and airflow rates result in higher power density and greater stack efficiency but lower net power from the fuel cell due to the higher power consumption for the balance of plant components. High airflow rates also produce more water causing mass transport limitation and fuel cell degradation by water accumulation in the gas diffusion layer and catalyst layer. High hydrogen rates can help by having more frequent purging from the anode side, but it can cause dehydration on the cell and consequently fuel cell degradation.

The temperature of the fuel cell also needs to be controlled (through a fan or heat-exchanger/radiator) in the optimum operating

range to keep the humidity level in the membrane. As was previously shown, a higher temperature than the operating range can cause dehydration, shrinkage, wrinkles, and even rupture in the membrane. The humidity of the reactants needs to be controlled (through humidifiers) to maintain the membrane hydrated and efficient water distribution to avoid dehydration or flooding. Currently, the state of the art is using a self-humidifying fuel cell as the one used on the Toyota Mirai to reduce the balance of plant cost (Yoshida and Kojima 2015). Finally, the fuel cell power needs to be regulated using DC/DC converters since the voltage changes with load power. In addition the converter is responsible for enforcing the current split and can be used to avoid abrupt transients or changes in fuel cell power demand to avoid fuel cell degradation. The goal is to operate the fuel cell at its maximum efficiency point within most of its operation.

Power Split

Different control strategies have been used to determine the optimal power split required for an FCV. The overall hydrogen consumption of the fuel cell vehicle needs to be minimized to achieve efficient fuel cell and vehicle operation. Generally, the cost function consists of minimizing the hydrogen consumption over an entire trip:

$$J = \int \dot{m}_f dt = \frac{I_{fc} n_{fc} M_{H_2}}{2F} \quad (1)$$

where J is the cost, $\dot{m}_f$ is the hydrogen consumption, $M_{H_2} = 2.016 \times 10^{-3} \frac{kg}{mol}$ is the hydrogen molar mass, and $F = 96,485 \frac{C}{mol}$ is the Faraday's constant. This cost function can have other terms to minimize and weights to penalized these terms. The limitation of these strategies is that the driving cycle of the vehicle needs to be known beforehand. Other formulations consist of defining an instantaneous cost function, which is updated with time. The limitation with the instantaneous cost function is that the models and formulation need to be as simple as possible to avoid the high computational cost.

Fuel Cell Vehicle Optimization and Control, Fig. 4 Schematic of simple proportional-integral control implementation

Rule-Based Control (RBC) Strategies

Rule-based strategies consist of rules based on experience with the goal to obtain an efficient power split between the fuel cell and an energy source storage such as battery or capacitor. These rules are easy to implement, but it is hard to determine whether they are optimal or not since they aim at maintaining a desired battery state of charge and not necessarily minimizing the overall energy consumption. The key point here is that the usefulness of consuming battery energy at a given point in time depends on future energy (hydrogen) used later to supplement this energy. The instantaneous conditions for the power split are thus hard to decide. Examples of rule-based strategies are proportional-integral control as shown in Fig. 4.

A proportional-integral (PI) controller is a feedback control loop that consists in calculating the error ($e(t) = r - y(t)$) between a reference value $r = SOC_{ref}$ and the output of the system $y(t) = SOC$. The SOC_{ref} is based on rules derived heuristically and aims to balance the use of battery to offset the use of FC and hence hydrogen. These rules are often expressed via IF-THEN rules and membership functions, which define certain situations and conditions that would enable either one or two energy sources between the main and the auxiliary energy sources. This rule-based method has become popular due to the easy implementation of simple rules without having to understand the complexity of the problem completely (Daud et al. 2017). Many researchers have implemented fuzzy logic controllers in FCV (Xiao et al. 2012). Once the rules guide to a fixed or slowly varying

reference battery state of charge, the remaining tuning relies on classical control techniques. Due to their low computational load, rule-based strategies can be easily implemented in real time in a FCV. The Toyota Mirai power split can be deduced from Arg (2018) and the modeling work of Davis and Hayes (2019). The Mirai strategy consists of a set of basic rules where the fuel cell is turned off during braking and idling. During driving conditions, the energy management is achieved through a load-following strategy that maintains the battery state of charge. Despite having a strong load following energy management, Davis and Hayes (2019) showed in simulations lower fuel cell degradation compared to a more load-leveling strategy.

In subsequent sections, we discuss how the battery state of charge can be defined based on an equivalent consumption minimization strategy. In either case, tuning the PI controller gains when the reference state of charge varies can be challenging. A proportional-integral controller was implemented in Wang et al. (2015) for full hybrid power system. The system included a PEMFC Horizon H-100, lithium-ion battery pack, and DC/DC unidirectional and bidirectional converter. The system's states consist of the inductor current and the output voltage of the DC/DC converter. The fuel cell model consisted of an equivalent electrical circuit with a variable double layer capacitor to display the transient characteristics. As typically done in such power split controllers, the fuel cell operating temperature was kept constant at 60 °C. The fuel cell auxiliary components were not specified, and neither the battery nor the fuel cell degradation was considered.

Fuel Cell Vehicle Optimization and Control, Fig. 5 In the dynamic programming (DP) and Pontryagin's minimum principle (PMP) formulation in Fares et al. (2015) and Zheng and Cha (2017), fuel cell power is used as an input (P_{fc}) and state of charge (SOC) as a state

F

Dynamic Programming (DP)

Dynamic programming (DP) is a numerical method that finds the optimal control sequence that minimizes a given cost function, in this case hydrogen consumption given constraints and a desired final battery state of charge. Since the optimal decision at every instant depends on the future demands and constraints, DP starts from the final step and propagates backward assuming knowledge of the entire load trajectory. Different papers applying DP have been developed with schemes similar to Fig. 5. In Fares et al. (2015), lookup tables based on experimental testing of an actual fuel cell (FC) test bench and the fuel cell power include the auxiliary power of the components used, such as water pumps, air-conditioner, and compressor. The operating temperature of the fuel cell is not specified. It is shown that the weighted DP improves hydrogen consumption compared to a state machine control algorithm for a fuel cell battery vehicle. However, only Matlab/Simulink simulations were performed.

Pontryagin's Minimum Principle (PMP)

Even though DP gives the optimal solution, its computational time exponentially increases as the number of states increases. Therefore, Pontryagin's minimum principle (PMP) can be an alternative solution to solve the control problem on FCVs. PMP consists of solving a set of conditions necessary for optimality. In Zheng and Cha (2017), PMP used fuel cell power as an input (P_{fc}) and state of charge (SOC) as

a state. A schematic of this is in Fig. 5. The cooling system is composed of a compressor and other auxiliary components. Degradation of the batteries and fuel cells was not considered, but a comparison between PMP to a rule-based energy management strategy was performed with respect to lower hydrogen consumption.

Equivalent Consumption Minimization Strategy (ECMS)

The ECMS has been proven to be equivalent under certain conditions to Pontryagin's minimum principle. This is a heuristic method that consists of reducing the global minimization problem into an instantaneous minimization problem. It is solved at each instant, only using a weighted value of the electric energy and on the actual energy flow in the powertrain. In Zhang et al. (2017), energy management using ECMS was used for a fuel cell hybrid vehicle using batteries and a supercapacitor. The ECMS only considered an optimum power of the fuel cell and battery by adding a penalty factor in terms of the battery SOC and fuel cell's mean efficiency. Fuel cell and battery degradation are not considered, and the simulation tool is not specified. More importantly, the FC system assumes a constant power of 11 kW for the total power of the auxiliary components, namely, an air-conditioner and a compressor. The fuel cell model consists of lookup tables, but the operating temperature is not specified pointing to the need for more comprehensive effort and experimentation for this promising work.

Model Predictive Control (MPC)

MPC uses model prediction to satisfy constraints on the input and output variables and measurements to adjust the actions (Seborg et al. 2011). MPC was used for buses and other applications that depend on the dynamic response of fuel cell and batteries (He et al. 2020). Many comparisons of the performance of a battery charge control, fuel cell dynamics, and fuel cell thermal dynamics were performed. These constraints were applied to avoid fuel cell degradation. The simulation results explored these constraints and their effect on hydrogen consumption, including auxiliary component losses for the cooling system.

Machine Learning

Machine learning consists of tools that detect patterns in data, and these patterns are used to predict future behavior or perform decisions under uncertainty. This method has been used, despite requiring large amounts of data, because of the excellent performance of trained models on the FCV. Reinforcement learning was used in Hsu et al. (2016) for the dynamic energy management of an FCV with batteries. This learning method consists of an agent observing the behavior of the data and updating the values of the parameters of the model through a reward function. One experiment where the reward function only accounts for charge sustaining SOC is included in Hsu et al. (2016). It was possible to show that on different driving cycles, reduced hydrogen consumption was achieved compared to the first experimental formulation.

Needs and Important Directions

Future work should use models that weigh the auxiliary losses and cost associated with membrane hydration and other physical phenomena that accelerate degradation to inform optimal control strategies (Goshtasbi and Ersal 2020) and total cost of ownership. Experimental validation on test benches or FCVs should also be performed to validate optimal control strategies

that consider auxiliary losses (Siegel et al. 2018). To reduce the cost of FCVs, the sizing of the FC and the battery need to be addressed for various drive cycles as in Sundström and Stefanopoulou (2007). Last but not least, connectivity and automation will allow even higher gains for these advanced powertrains, as shown in Kim et al. (2020).

Fundamental Limitation of Feedback Control

Jie Chen

City University of Hong Kong, Hong Kong, China

Abstract

Feedback systems are designed to meet many different objectives. Yet, not all design objectives are achievable as desired due to the fact that they are often mutually conflicting and that system properties themselves may impose design constraints and thus limitations on the performance attainable. An important step in the control design process is then to assess and analyze what and how system characteristics may impose constraints and, accordingly, how to make tradeoffs between different objectives by judiciously navigating between the constraints. Fundamental limitation of feedback control is an area of research that addresses these constraints, limitations, and tradeoffs.

Keywords

Bode integrals · Design tradeoff · Performance limitation · Tracking and regulation limits

Introduction

Fundamental control limitations are referred to those intrinsic of feedback that can neither be overcome nor circumvent regardless how it may be designed. By this nature, the study of fundamental limitations dwells on a Hamletian question: Can or can't it be done? What can and cannot be achieved? What is the best and the worst possible? To be more specific, yet still general enough, at heart here are issues concerning the benefit and cost of feedback. We ask such questions as “(1) What system characteristics may impose inherent limitations regardless of controller design?”, “(2) What inherent

constraints may exist in design and what kind of tradeoffs are to be made?”, “(3) What are the best achievable performance limits?”, and “(4) How can the constraints, limitations, and limits be quantified in ways meaningful for control analysis and design?”. Needless to say, issues of this kind are very broad and in fact are omnipresent in science and engineering. Analogies can be made, for example, to Shannon’s theorems in communications theory, the Cramer-Rao bound in statistics, and Heisenberg’s uncertainty principle in quantum mechanics; they all address the fundamental limits and limitations, though for different problems and in different contexts. The search for fundamental limitations of feedback control, as such, may be considered a quest for an “ultimate truth” or the “law of feedback.”

For their fundamentality and importance, inquiries into control performance limitations have persisted over time and continue to be of vital interest. It is worth emphasizing, however, that performance limitation studies are not merely driven by intellectual curiosity, but are tantamount to better and more realistic feedback systems design and hence of tangible practical value. An analysis of performance limitations can aid control design in several aspects. First, it may provide a fundamental limit on the best performance attainable irrespective of controller design, thus furnishing a guiding benchmark in the design process. Secondly, it helps a designer assess what and how system properties may be inherently conflicting and thus pose inherent difficulties to performance objectives, which in turn helps the designer specify reasonable goals, and make judicious modifications and revisions on the design. In this process, the theory of fundamental control limitations promises to provide valuable insights and analytical justifications to long-held design heuristics and, indeed, to extend such heuristics further beyond. This has become increasingly more relevant, as modern control design theory and practice relies heavily on automated, optimization-based numerical routines and tools.

Systematic investigation and understanding of fundamental control limitations began with the classical work of Bode in the 1940s on

logarithmic sensitivity integrals, known as the Bode integrals. Bode’s work has had a lasting impact on the theory and practice of control and has inspired continued research endeavor dated most recently, leading to a variety of extensions and new results which seek to quantify design constraints and performance limitations by frequency-domain logarithmic integrals. On the other hand, the search for the best achievable performance is a natural goal, and indeed an innate instinct, in the study of optimal control problems, which has lend bounds on optimal performance indices defined under various criteria. Likewise, developments in this latter area of study have also been substantial and are continuing to branch to different problems and different system categories.

In this entry we attempt to provide a summary overview of the key developments in the study of fundamental limitations of feedback control. While the understanding on this subject has been compelling and the results are rather prolific, we focus on Bode-type integral relations and the best achievable performance limits, two branches of the study that are believed to be most well-developed. Roughly speaking, the Bode-type integrals are most useful for quantifying the inherent design constraints and tradeoffs in the frequency domain, while the performance results provide fundamental limits of canonical control objectives defined using frequency- and time-domain criteria. Invariably, the two sets of results are intimately related and reinforce each other. The essential message then is that despite its many benefits, feedback has its own limitations and is subject to various constraints. Feedback design, for that sake, requires oftentimes a hard tradeoff.

Control Design Specifications

We begin by introducing the basic notation to be used in the sequel. Let $\mathbb{C}_+ := \{z : \text{Re}(z) > 0\}$ denote the open right half plane (RHP) and $\overline{\mathbb{C}}_+$ the closed RHP (CRHP). For a complex number z , we denote its conjugate by $\bar{z}$. For a complex vector x , we denote its conjugate transpose by

x^H , and its Euclidean norm by $\|x\|_2$. The largest singular value of a matrix A will be written as $\bar{\sigma}(A)$. If A is a Hermitian matrix, we denote by $\bar{\lambda}(A)$ its largest eigenvalue. For any unitary vectors $u, v \in \mathbb{C}^n$, we denote by $\angle(u, v)$ the *principal angle* between the two one-dimensional subspaces, called the *directions*, spanned by u and v :

$$\cos \angle(u, v) := |u^H v|.$$

For a stable continuous-time system with transfer function matrix $G(s)$, we define its $\mathcal{H}_\infty$ norm by

$$\|G\|_\infty := \sup_{\operatorname{Re}(s) > 0} \bar{\sigma}(G(s)).$$

We consider the standard configuration of finite-dimensional linear time-invariant (LTI) feedback control systems given in Fig. 1. In this setup, P and K represent the transfer functions of the plant model and controller, respectively, r is a command signal, d a disturbance, n a noise signal, and y the output response. Define the open-loop transfer function, the sensitivity function, and the complementary sensitivity function by

$$L = PK, \quad S = (I + L)^{-1}, \quad T = L(I + L)^{-1},$$

respectively. Then the output can be expressed as

$$y = Sd - Tn + SP r.$$

The goal of feedback control design is to design a controller K so that the closed-loop system is stable and that it achieves certain performance specifications. Typical design objectives include:

Fundamental Limitation of Feedback Control, Fig. 1
Feedback configuration

- *Disturbance attenuation.* The effect of the disturbance signal on the output should be kept small, which translates into the requirement that the sensitivity function be small in magnitude at the frequencies of interest. For a single-input single-output (SISO) system, this mandates that

$$|S(j\omega)| < 1, \quad \forall \omega \in [0, \omega_1].$$

The sensitivity magnitude $|S(j\omega)|$ is to be kept as small as possible in the low-frequency range, where the disturbance signal concentrates.

- *Noise reduction.* The noise response should be reduced at the output. This requires that the complementary sensitivity function be small in magnitude at frequencies of interest. For a SISO system, the objective is to achieve

$$|T(j\omega)| < 1, \quad \forall \omega \in [\omega_2, \infty).$$

Similarly, the magnitude $|T(j\omega)|$ is desired to be small at high frequencies, since noise signals typically consist of significant high-frequency harmonics.

Moreover, feedback can be introduced to achieve many other objectives including regulation, command tracking, improved sensitivity to parameter variations, and, more generally, system robustness, all by manipulating the three key transfer functions: the open-loop transfer function, the sensitivity function, and the complementary sensitivity function.

The design and implementation of feedback systems, on the other hand, are also subject to many constraints, which include:

1. *Causality:* A system must be causal for it to be implementable. The causality requirement limits the means of compensation to those that are physically realizable; for example, no ideal filter can be used, and the system's relative degree and delay cannot be cancelled but must be preserved.

2. **Stability:** The closed-loop system must be stable. Mathematically, this dictates that every closed-loop transfer function must be bounded and analytic in CRHP.
3. **Interpolation:** There should be no unstable pole-zero cancelation between the plant and controller, in order to rid of hidden instability. The requirement is also necessary for system robustness, as in reality no perfect cancellation is possible. Thus, for a SISO system, it is necessary that

$$S(p_i) = 0, \quad T(p_i) = 1,$$

$$S(z_i) = 1, \quad T(z_i) = 0$$

at each CRHP pole p_i and zero z_i of the plant.

4. **Structural constraints:** These constraints arise from the feedback structure itself; for example, $S(s) + T(s) = 1$. The implication is that the closed-loop transfer functions cannot be independently designed, thus resulting in conflicting design objectives.

For a given plant, each of these constraints is unalterable and hence is fundamental, and each will constrain the performance attainable in one way or another. The question we face then is how the constraints may be captured in a form that is directly pertinent and useful to feedback design.

Bode Integral Relations

In the classical feedback control theory, Bode's gain-phase formula (Bode 1945) is used to express the aforementioned design constraints for SISO systems.

Bode Gain-Phase Integral *Suppose that $L(s)$ has no pole and zero in $\overline{\mathbb{C}}_+$. Then at any frequency ω_0 ,*

$$\angle L(j\omega_0) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{d \log |L(jv)|}{dv} \log \coth \frac{|v|}{2} dv,$$

where $v = \log(\omega/\omega_0)$.

A special form of the Hilbert transform, this gain-phase formula relates the gain and phase of the open-loop transfer function evaluated along the imaginary axis, whose implication may be explained as follows. In order to make the sensitivity response small in the low-frequency range, the open-loop transfer function is required to have a high gain; the higher, the better. On the other hand, for noise reduction and robustness purposes, we need to keep the loop gain low at high frequencies, the lower the better. Evidently, to maximize these objectives, we want the two frequency bands as wide as possible. This then requires a steep decrease of the loop gain and hence a rather negative slope in the intermediate frequency range. Take ω_0 as the crossover frequency. The gain-phase relationship tells that a more negative derivative of the loop gain near ω_0 (implying a faster decrease of the gain) will lead to a more negative phase, thus driving the phase closer to the negative 180 degrees, namely, the critical point of stability. It consequently reduces the phase margin and may even cause instability. As a result, the gain-phase relationship demonstrates a conflict between the two design objectives. It is safe to claim that much of the classical feedback design theory came as a consequence of this simple relationship, aiming to shape the open-loop frequency response in the crossover region by trial and error, using lead or lag filters.

The gain-phase formula allows us to quantify, indirectly, the closed-loop design constraints and performance tradeoffs via open-loop data and by loopshaping design. In doing so, the design specifications imposed on closed-loop transfer functions are translated approximately into the requirements on the open-loop transfer function, and the tradeoff between different design goals is achieved by shaping the open-loop gain and phase. A more direct vehicle to accomplish this same goal is Bode's sensitivity integral (Bode 1945).

Bode Sensitivity Integrals *Let $p_i \in \mathbb{C}_+$ be the unstable poles and $z_i \in \mathbb{C}_+$ the nonminimum phase zeros of $L(s)$. Suppose that the closed-loop system in Fig. 1 is stable.*

- (i) If $L(s)$ has relative degree greater than one, then

$$\int_0^\infty \log |S(j\omega)| d\omega = \pi \sum_i p_i.$$

- (ii) If $L(s)$ contains no less than two integrators, then

$$\int_0^\infty \frac{\log |T(j\omega)|}{\omega^2} d\omega = \pi \sum_i \frac{1}{z_i}.$$

Bode's original work concerns the sensitivity integral for open-loop stable systems only. The integral relations shown herein, which are attributed to Freudenberg and Looze (1985) and Middleton (1991), respectively, provide generalizations to open-loop unstable and nonminimum phase systems.

Why are Bode integrals important? What is the hidden message behind the mathematical formulas? Simply put, the Bode sensitivity integral relation (*vis-a-vis* the complementary sensitivity integral relation) exhibits that a feedback system's sensitivity must abide some kind of conservation law or invariance principle: the integral of the logarithmic sensitivity magnitude over the entire frequency range must be a nonnegative constant, determined by the open-loop unstable poles. This principle mandates a tradeoff between sensitivity reduction and sensitivity amplification in different frequency bands. Indeed, to achieve disturbance attenuation at low frequencies, the logarithmic sensitivity magnitude must be kept below zero db, the lower the better. For noise reduction and system robustness, however, the sensitivity magnitude must decrease to zero db at high frequencies. Since, in light of the sensitivity integral relation, the total area under the logarithmic sensitivity magnitude curve is nonnegative, the logarithmic magnitude must rise above zero db in the intermediate frequency range so that under its curve, the positive and negative areas may cancel each other to yield a nonnegative value. As such, an undesirable sensitivity amplification occurs, resulting in a fundamental tradeoff between the desirable sensitivity reduction and

the undesirable sensitivity amplification, known colloquially as the *waterbed effect*.

MIMO Integral Relations

For a multi-input multi-output (MIMO) system depicted in Fig. 1, the sensitivity and complementary sensitivity functions, which now are transfer function matrices, satisfy similar interpolation constraints: at each RHP pole p_i and zero z_i of $L(s)$, the equations

$$\begin{aligned} S(p_i)\eta_i &= 0, & T(p_i)\eta_i &= \eta_i, \\ w_i^H S(z_i) &= w_i^H, & w_i^H T(z_i) &= 0 \end{aligned}$$

hold with some unitary vectors η_i and w_i , where η_i is referred to as a *right pole direction vector* associated with p_i and w_i a *left zero direction vector* associated with z_i . The frequency-domain design specifications are also similar but are now quantified using the singular values of the closed-loop transfer function matrices. Specifically, the disturbance attenuation and noise reduction requirements may now be specified as

$$\bar{\sigma}[S(j\omega)] < 1, \quad \forall \omega \in [0, \omega_1]$$

and

$$\bar{\sigma}[T(j\omega)] < 1, \quad \forall \omega \in [\omega_2, \infty),$$

respectively.

The classical Bode integrals are only applicable to SISO systems. While it seems both natural and tempting, the extension of Bode integrals to MIMO systems has been highly nontrivial a task. Deep at the root is the complication resulted from the directionality properties of MIMO systems. Unlike in a SISO system, the measure of frequency response magnitude is now the largest singular value of a transfer function matrix, which represents the worst-case amplification of energy-bounded signals, a direct counterpart to the gain of a scalar transfer function. This fact alone casts a fundamental difference and poses a formidable obstacle. From a technical standpoint, the logarithmic function of the largest singular value is no longer a harmonic function

as in the SISO case, but only a subharmonic function. Much to our chagrin then, familiar tools from the analytic function theory, such as Cauchy and Poisson theorems, the very backbones in developing the scalar Bode integrals, cease to be useful. Indeed, the lack of the comparably strong analyticity of singular value functions is perhaps one of the main barriers why MIMO versions of the Bode integrals remained an open, unanswered question for several decades. Nevertheless, it remains possible to extend Bode integrals in their essential spirit. Advances are made by Chen (1995, 1998, 2000).

MIMO Bode Sensitivity Integrals *Let $p_i \in \mathbb{C}_+$ be the unstable poles of $L(s)$ and $z_i \in \mathbb{C}_+$ the nonminimum phase zeros of $L(s)$. Suppose that the closed-loop system in Fig. 1 is stable.*

- (i) *If $L(s)$ has relative degree greater than one, then*

$$\int_0^\infty \log \bar{\sigma}(S(j\omega)) d\omega \geq \pi \bar{\lambda} \left(\sum_i p_i \zeta_i \zeta_i^H \right).$$

- (ii) *If $L(s)$ contains no less than two integrators, then*

$$\int_0^\infty \frac{\log \bar{\sigma}(T(j\omega))}{\omega^2} d\omega \geq \pi \bar{\lambda} \left(\sum_i \frac{1}{z_i} \xi_i \xi_i^H \right)$$

where ζ_i and ξ_i are some unitary vectors related to the right pole direction vectors associated with p_i and the left zero direction vectors associated with z_i , respectively.

From these extensions, it is evident that same limitations and tradeoffs on the sensitivity and complementary sensitivity functions carry over to MIMO systems; in fact, both integrals reduce to the scalar Bode integrals when specialized to SISO systems. Yet there is something additional to and unique of MIMO systems: the integrals now depend on not only the locations but also the directions of the zeros and poles. In particular, it can be shown that they depend on the mutual orientation of these directions and the dependence can be explicitly characterized geometrically by

the principal angles between the directions. This new phenomenon, which finds no analog in SISO systems, thus highlights the important role of directionality in sensitivity tradeoff and more generally, in the design of MIMO systems.

A more sophisticated and, accordingly, more informative variant of Bode integrals is the Poisson integral for sensitivity and complementary sensitivity functions (Freudenberg and Looze 1985), which can be used to provide quantitative estimates of the waterbed effect. MIMO versions of Poisson integrals are also available (Chen 1995, 2000).

Frequency-Domain Performance Bounds

Performance bounds complement the integral relations and provide fundamental thresholds to the best possible performance ever attainable. Such bounds are useful in providing benchmarks for evaluating a system's performance prior to and after controller design. In the frequency domain, fundamental limits can be specified as the minimal peak magnitude of the sensitivity and complementary sensitivity functions achievable by feedback or, formally, the minimal achievable $\mathcal{H}_\infty$ norms:

$$\gamma_{\min}^S := \inf \{ \|S(s)\|_\infty : K(s) \text{ stabilizes } P(s) \},$$

$$\gamma_{\min}^T := \inf \{ \|T(s)\|_\infty : K(s) \text{ stabilizes } P(s) \}.$$

Drawing upon *Nevanlinna-Pick interpolation* theory for analytic functions, one can obtain exact performance limits under rather general circumstances (Chen 2000).

$\mathcal{H}_\infty$ Performance Limits *Let $z_i \in \mathbb{C}_+$ be the nonminimum phase zeros of $P(s)$ with left direction vectors w_i and $p_i \in \mathbb{C}_+$ the unstable poles of $P(s)$ with right direction vectors η_i , where z_i and p_i are all distinct. Then,*

$$\gamma_{\min}^S = \gamma_{\min}^T = \sqrt{1 + \bar{\sigma}^2 \left(Q_p^{-1/2} Q_{zp} Q_z^{-1/2} \right)},$$

where Q_z , Q_p , and Q_{zp} are the matrices given by

$$Q_z := \left[\frac{w_i^H w_j}{z_i + \bar{z}_j} \right], \quad Q_p := \left[\frac{\eta_i^H \eta_j}{\bar{p}_i + p_j} \right],$$

$$Q_{zp} := \left[\frac{w_i^H \eta_j}{z_i - p_j} \right].$$

More explicit bounds showing how zeros and poles may interact to have an effect on these limits can be obtained, e.g., as

$$\gamma_{\min}^S = \gamma_{\min}^T \geq \sqrt{\sin^2 \angle(w_i, \eta_j) + \left| \frac{p_j + \bar{z}_i}{p_j - z_i} \right|^2 \cos^2 \angle(w_i, \eta_j)},$$

F

which demonstrates once again that the pole and zero directions play an important role in MIMO systems. Note that for RHP poles and zeros located in the close vicinity, this bound can become excessively large, which serves as another vindication why unstable pole-zero cancelation must be prohibited. Note also that for MIMO systems, however, whether near pole-zero cancelation is problematic depends additionally on the mutual orientation of the pole and zero directions.

The bounds given above are the solutions to the well-known *sensitivity minimization problem* in the $\mathcal{H}_\infty$ optimal control theory. For SISO systems, they reduce to Zames and Francis (1983) and Khargonecker and Tannenbaum (1985)

$$\gamma_{\min}^S \geq \prod_i \left| \frac{z + \bar{p}_i}{z - p_i} \right|,$$

where p_i are the unstable poles and z is a non-minimum phase zero of $P(s)$, and

$$\gamma_{\min}^T \geq \prod_i \left| \frac{p + \bar{z}_i}{p - z_i} \right|,$$

with z_i being the nonminimum phase zeros and p an unstable pole of $P(s)$. For more general, the so-called weighted sensitivity minimization problem, less explicit, computational formulas are available to determine the best achievable sensitivity and complementary sensitivity magnitudes.

Time-Domain Tracking and Regulation Limits

Tracking and regulation are two canonical objectives of servo mechanisms and constitute chief criteria in assessing the performance of feedback control systems (Kwakernaak and Sivan 1972; Qiu 1993). Understandings gained from these problems shed light into more general issues indicative of feedback design. In its full generality, a tracking system can be depicted as in Fig. 2, in which a 2-DOF (degree of freedom) controller $K = \begin{bmatrix} K_1 & K_2 \end{bmatrix}$ is designed for the output z to track a given reference input r , based on the feedforward of the reference signal r and the feedback of the measured output y :

$$u = K_1 r + K_2 y.$$

The tracking performance is defined in the time domain by the integral square error

$$J = \int_0^\infty \|z(t) - r(t)\|_2^2 dt,$$

Typically, we take r to be a step signal, which in the MIMO setting corresponds to a unitary constant vector, i.e., $r(t) = v$, $t > 0$ and $r(t) = 0$, $t < 0$, where $\|v\|_2 = 1$. We assume P to be LTI. But K can be arbitrarily general, as long as it is causal and stabilizing. We want z to not only track r asymptotically but also minimize J . But how small can it be?

Fundamental Limitation of Feedback Control, Fig. 2
2-DOF tracking control structure

Fundamental Limitation of Feedback Control, Fig. 3
2-DOF regulator

For the regulation problem, a general setup is given in Fig. 3. Likewise, K may be taken as a 2-DOF controller. The control energy is measured by the quadratic cost

$$E = \int_0^\infty \|u(t)\|_2^2 dt.$$

We consider a disturbance signal d , typically taken as an impulse signal, $d(t) = v\delta(t)$, where v is a unitary vector. In this case, the disturbance can be interpreted as a nonzero initial condition, and the controller K is to regulate the system's zero-input response. Similarly, we assume that P is LTI but allow K to be any causal, stabilizing controller. Evidently, for a stable P , the problem is trivial; the response will restore itself to the origin, and thus no energy is required. But what if the system is unstable? How much energy does the controller must generate to combat the disturbance? What is the smallest amount of energy required? These questions are answered by the best achievable limits of the tracking and regulation performance (Chen et al. 2000, 2003).

Tracking and Regulation Performance Limits

Let $p_i \in \mathbb{C}_+$ and $z_i \in \mathbb{C}_+$ be the RHP poles and zeros of $P(s)$, respectively. Then,

$$\inf\{E: K \text{ stabilizes } P(s)\} = \sum_i p_i \cos^2 \angle(\zeta_i, v),$$

$$\inf\{J: K \text{ stabilizes } P(s)\} = \sum_i \frac{1}{z_i} \cos^2 \angle(\xi_i, v),$$

where ζ_i and ξ_i are some unitary vectors related to the right pole direction vectors associated with p_i and the left zero direction vectors associated with z_i , respectively.

It becomes instantly clear that the optimal performance depends on both the pole/zero locations and their directions. In particular, it depends on the mutual orientation between the input and pole/zero directions. This sheds some interesting light. Take the tracking performance for an example. For a SISO system, the minimal tracking error can never be made zero for a nonminimum phase plant; in other words, perfect tracking can never be achieved. Yet this is possible for MIMO systems, when the input and zero directions are appropriately aligned, specifically when they are orthogonal. Similarly, for SISO unstable systems, a certain amount of energy is necessary to achieve regulation, and the minimal regulation energy cannot be zero. But for a MIMO system, it can be zero; no energy is required at all when the disturbance and pole directions are orthogonal. While seemingly somewhat counterintuitive, this scenario is in fact intuitively sensible; it merely says that the disturbance happens to enter from a direction where it does not excite the unstable modes, and so the system will be at rest all by itself.

Interestingly, the optimal performance in both cases can be achieved by LTI controllers, though allowed to be more general. As a consequence, the results provide the true fundamental limits that cannot be further improved by any causal feedback, using any other more general control laws such as nonlinear, time-varying feedforward and feedback. They are simply the best one can ever hope for, and the LTI controllers turn out to be optimal, provided that the plant itself is LTI. Moreover, it is worth pointing out the optimal tracking and regulation performance problems posed herein are formulated in an extreme, idealistic setting, with no practical consideration. The optimal controllers so obtained are likely to result

in excessive energy or magnitude peaking. This, of course, is seldom possible nor viable in practice. Tracking and regulation performances in more realistic formulations that take into account additional constraints, such as constraints on the control energy, were considered in, e.g., Chen et al. (2003).

Summary and Future Directions

Whether in time or frequency domain, while the results under survey may differ in forms and contexts, they unequivocally point to the fact that inherent constraints exist in feedback design, and fundamental limitations will necessarily arise, limiting the performance achievable regardless of controller design. Such constraints and limitations are exacerbated by the nonminimum phase zeros and unstable poles in the system. Understanding of these constraints and limitations proves essential to the success of control design. Additional perspectives and insights into this topic can be found in, e.g., Seron (1997), Åström (2000), and Chen et al. (2019).

Both the Bode-type integrals and the performance bounds presented herein admit representations in terms of input-output spectral densities or such information-theoretic measures as *entropy rates*, offering alternative interpretations based on the spectral or information contents of a system's input and output signals, instead of the system's transfer functions. The information-theoretic representation is especially susceptible to characterizing constraints that arise in information-limited and, more generally, networked feedback systems, where noisy and limited information transmission within the feedback loop results in additional limitations on the achievable control performance. The study of such systems requires incorporation of information and communication constraints into control performance analysis and, for that matter, the integration of information and control theories. We refer this undertaking to Fang et al. (2017) and Chen et al. (2019).

For both its intrinsic appeal and practical importance, the study of fundamental control limitations has been a topic of enduring vitality,

and the interest will continue unabated. New technological advances and applications in networked control, multi-agent systems, complex networks, cyber physical systems, and Internet of things (IoT) will usher in new issues to the study of control performance limitations. How control and communication constraints in such large-scale, distributed interconnected networks manifest themselves and how they may be characterized from a control performance perspective present daunting challenges. Performance limitation studies will undoubtedly find expansion and outgrowth into these broad fields. The integration of information and control theories, long awaited since the time of Bode, Shannon, and Wiener, is only beginning to emerge and will likely require a conceptual leap and new mathematical tools.

Game Theory for Security

Tansu Alpcan
Department of Electrical and Electronic
Engineering, The University of Melbourne,
Melbourne, VIC, Australia

Abstract

Game theory provides a mature mathematical foundation for making security decisions in a principled manner. Security games help formalizing security problems and decisions using quantitative models. The resulting analytical frameworks lead to better allocation of limited resources and result in more informed responses to security problems in complex systems and organizations. The game-theoretic approach to security is applicable to a wide variety of cyberphysical systems and critical infrastructures such as electrical power systems, financial services, transportation, data centers, and communication networks.

Cyberphysical system security · Complex
systems

Introduction

Securing a cyberphysical system involves making numerous decisions whether the system is a computer network, is part of a business process in an organization, or belongs to a critical infrastructure. One has to decide on, for example, how to configure sensors for surveillance, collect further information on system properties, and allocate resources to secure a critical segment or who should be able to access a specific function in the system. The decision-maker can be, depending on the setting, a regular employee, a system administrator, or the chief technical officer of an organization. In many cases, the decisions are made automatically by a computer program such as allowing a packet pass the firewall or filtering it out. The time frame of these decisions exhibits a high degree of variability from milliseconds, if made by software, to days and weeks, e.g., when they are part of a strategic plan. Each security decision has a cost, and any decision-maker is always constrained by limited amount of available resources. More importantly, each decision carries a security risk that needs to be taken into account when balancing the costs and the benefits.

Security games facilitate building analytical models which capture the interaction between

malicious attackers, who aim to compromise networks, owners, or administrators defending them. Attacks exploiting vulnerabilities of the underlying systems and defensive countermeasures constitute the moves of the game. Cost-benefit analysis of potential attacks and defenses, including perceived risks, provides the criteria, which the players act upon when choosing actions. Thus, the strategic struggle between attackers and defenders is formalized quantitatively based on the solid mathematical foundation provided by the field of game theory.

An important aspect of security games is the allocation of limited available resources from the perspectives of both attackers and defenders. If the players had access to unlimited resources (e.g., time, computing power, bandwidth), then the resulting security games would be trivial. In real-world security settings, however, both attackers and defenders have to act strategically and make numerous decisions when allocating their respective resources. Unlike in an optimization approach, security games take into account the decisions and resource limitations of both the attackers and the defenders.

Security Games

A security game is defined with four components: the players, the set of possible actions or strategies for each player, the outcome of the game for each player as a result of their action-reaction, and information structures in the game. The players have their own (selfish or malicious) motivations and inherent resource constraints. Based on these motivations and information available, they choose most beneficial strategies for themselves and act accordingly. The actions of players could be concurrent or sequential in which a player takes the lead and the other player follows. Hence, game theory helps analyzing decision-makers interacting on a system in a quantitative manner.

An Example Formulation

A simple security game can be formulated as a two-player and strategic (noncooperative) one,

Game Theory for Security, Fig. 1 A simple, two-player security game

where one player is the *attacker* and the other one is the *defender* protecting a system. Let the discrete actions available to the attacker and the defender be $\{a, b\}$ and $\{c, d\}$, respectively. Each attack-defense pair leads to one of the outcome pairs for the attacker and the defender $\{(x1, y1), (x2, y2), (x3, y3), (x4, y4)\}$, which represent the respective player's gains (or losses). This classic security game is depicted graphically in Fig. 1. It can also be represented as a matrix game as follows, where the attacker is the row player and the defender is the column player:

$$\begin{array}{cc} & \begin{matrix} (c) & (d) \end{matrix} \\ \begin{bmatrix} (x1, y1) & (x2, y2) \\ (x3, y3) & (x4, y4) \end{bmatrix} & \begin{matrix} (a) \\ (b) \end{matrix} \end{array}$$

If the decision variables of the players are continuous, for example, $x \in [0, a]$ and $y \in [0, c]$ denote attack and defense intensity, respectively, and then the resulting continuous-kernel game is described using functions instead of a matrix. Then, $J^{\text{attacker}}(x, y)$ and $J^{\text{defender}}(x, y)$ quantify the cost of the attacker and defender as a function of their actions, respectively.

Security Game Types

In its simplest formulation, the conflict between those defending a system and malicious attackers targeting it can be modeled as a two-person zero-sum security game, where the loss of a player is the gain of the other. Alternatively, two- and multi-person non-zero-sum security games generalize this for capturing a broader range of interactions. Static game formulations and their repeated versions are helpful for modeling myopic behavior of players in fast-changing

situations where planning future actions is of little use. In the case where the underlying system dynamics are predictable and available to the players, dynamic security game formulations can be utilized. If there is an order of actions in the game, for example, a purely reactionary defender, then leader-follower games can be used to formulate such cases where the attacker takes the lead and the defender follows.

Within the framework of security games, the concept of Nash equilibrium, where no player gains from deviating from its own Nash equilibrium strategy if others stick with theirs, provides a solid foundation. However, there are refinements and additional solution concepts when the game is dynamic or when there is more than one Nash equilibrium or information limitations in the game. These constitute an open and ongoing research topic. A related research question is the design of security games to ensure a favorable outcome from a global perspective while taking into account the independence of individual players in their decisions.

In certain cases, it is useful to analyze the player interactions in multiple layers. For example, in some security games, there may be defenders and malicious attackers trying to influence a population of other players by indirect means. In order to circumvent modeling complexity of the problem, evolutionary games have been suggested. While evolutionary games forsake modeling individual player actions, they provide valuable insights to collective behavior of populations of players and ensure tractability. Such models are useful, for example, in the analysis of various security policies affecting many users or security of large-scale critical systems.

Another important aspect of security decisions is the availability and acquisition of information on the properties of the system at hand, the actions of other players, and the incentives behind them. Clearly, the amount of information available has a direct influence on the decisions, yet acquiring information is often costly or even infeasible in some cases. Then, the decisions have to be made with partial information, and information collection becomes part of the decision process itself, creating a complex feedback loop.

Statistical or machine learning techniques and system identification are other useful methods in analysis of security games where players use the acquired information iteratively to update their own model of the environment and other players. The players then decide on their best courses of action. Existing work on fictitious play and reinforcement learning methods such as (deep) Q-learning are applicable and useful. A unique feature of security games is the fact that players try to hide their actions from others. These observability issues and distortions in observations can be captured by modeling the interaction between players who observe each other's actions as a noisy communication channel.

Applications

An early application of the decision and game-theoretic approach has been to the well-defined jamming problem, where malicious attackers aim to disrupt wireless communication between legitimate parties (Zander 1990; Kashyap et al. 2004). Detection of security intrusion and anomalies due to attacks is another problem, where the interaction between attackers and defenders has been modeled successfully using game theory (Alpcan and Başar 2011; Kodialam and Lakshman 2003; Han et al. 2017). Decision and game-theoretic approaches have been applied to a broad variety of networked system security problems such as security investments in organizations (Miura-Ko et al. 2008; Fielder et al. 2014), (location) privacy (Buttayan and Hubaux 2008; Kantarcioglu et al. 2011), distributed attack detection, attack trees and graphs, adversarial control (Altman et al. 2010), and topology planning in the presence of adversaries (Gueye et al. 2010), transportation security (Pita et al. 2009), as well as to other types of security games and decisions. Security games have been used to investigate cyberphysical security of (smart) power grid (Law et al. 2012). The well-cited survey paper Manshaei et al. (2013) presents an extensive segment of the literature on the subject.

The proceedings of the Conferences on Decision and Game Theory for Security (GameSec)

have been published as edited volumes in Lecture Notes for Computer Science (LNCS) since 2010. *GameSec* (www.gamesec-conf.org) has emerged as one of the main conferences that brings together active researchers focusing on security applications of game theory, and its proceedings contain the latest research results in this field. Increasingly, there are sessions involving papers on game theory in prominent machine learning conferences, which focus more on computational aspects of game theory often in relation to adversarial machine learning.

Analytical risk management is a related emerging research subject. Analytical methods and game theory have been applied to the field only recently but with increasing success (Guikema 2009; Mounzer et al. 2010). Another emerging topic is the adversarial mechanism design (Chorppath and Alpcan 2011; Roth 2008), where the goal is to design mechanisms resistant to malicious behavior.

Summary and Future Directions

Game theory provides quantitative methods for studying the players in security problems such as attackers, defenders, and users as well as their interaction and incentives. Hence, it facilitates making decisions on the best courses of action in addressing security problems while taking into account resource limitations, underlying incentive mechanisms, and security risks. Thus, security games and associated quantitative models have started to replace the prevalent ad hoc decision processes in a wide variety of security problems from safeguarding critical infrastructure to risk management, trust, and privacy in networked systems.

Game theory for security is a young and active research area as evidenced by the conference series “Conference on Decision and Game Theory for Security” (www.gamesec-conf.org) celebrating its tenth edition in 2019, the increasing number of journal and conference articles, as well as the published books (Alpcan and Başar 2011; Buttyan and Hubaux 2008; Tambe 2011).

Game Theory: A General Introduction and a Historical Overview

Tamer Başar

Coordinated Science Laboratory, Department of Electrical and Computer Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Abstract

This entry provides an overview of the aspects of game theory that are covered in this *Encyclopedia*, which includes a broad spectrum of

topics on static and dynamic game theory. The entry starts with a brief overview of game theory, identifying its basic ingredients, and continues with a brief historical account of the development and evolution of the field. It concludes by providing pointers to other entries in the *Encyclopedia* on game theory and a list of references.

Keywords

Game theory · Dynamic games · Historical evolution of game theory · Nash equilibrium · Stackelberg equilibrium · Cooperation · Evolutionary games

What Is Game Theory?

Game theory deals with strategic interactions among multiple decision-makers, called *players* (and in some contexts, *agents*), with each player's preference ordering among multiple alternatives captured in an objective function for that player, which she either tries to maximize (in which case the objective function is a *utility* function or a *benefit* function) or minimize (in which case we refer to the objective function as a *cost* function or a *loss* function). For a nontrivial game, the objective function of a player depends on the choices (*actions* or equivalently *decision variables*) of at least one other player, and generally of all the players, and hence a player cannot simply optimize her own objective function independent of the choices of the other players. This thus brings in a coupling among the actions of the players and binds them together in decision-making even in a noncooperative environment. If the players are able to enter into a cooperative agreement so that the selection of actions or decisions is done collectively and with full trust and so that all players would benefit to the extent possible, then we would be in the realm of *cooperative game theory*, where issues such as bargaining and characterization of *fair* outcomes, coalition formation, and excess utility distribution are of relevance; an entry in this *Encyclopedia* (by Haurie) discusses cooperation and cooperative outcomes

in the context of dynamic games. Other aspects of cooperative game theory can be found in several standard texts on game theory, such as Owen (1995), Vorob'ev (1977), or Fudenberg and Tirole (1991). See also the 2009 survey entry Saad et al. (2009), which emphasizes applications of cooperative game theory to communication networks.

If no cooperation is allowed among the players, then we are in the realm of *noncooperative game theory*, where first, one has to introduce a satisfactory solution concept. Leaving aside for the moment the issue of how the players can reach such a solution point, let us address the issue of what would be the minimum features one would expect to see there. To first order, such a solution point should have the property that if all players but one stay put, then the player who has the option of moving away from the solution point should not have any incentive to do so because she cannot improve her payoff. Note that we cannot allow two or more players to move collectively from the solution point, because such a collective move requires cooperation, which is not allowed in a noncooperative game. Such a solution point where none of the players can improve her payoff by a unilateral move is known as a *noncooperative equilibrium* or *Nash equilibrium*, named after John Nash, who introduced it and proved that it exists in finite games (i.e., games where each player has only a finite number of alternatives), over 60 years ago; see Nash (1950, 1951). This result and its various extensions for different frameworks as well as its computation (both offline and online) are discussed in several entries in this *Encyclopedia*. Another noncooperative equilibrium solution concept is the *Stackelberg equilibrium*, introduced in von Stackelberg (1934), and predating the Nash equilibrium, where there is a hierarchy in decision-making among the players, with some of the players, designated as *leaders*, having the ability to first announce their actions (and make a commitment to play them), and the remaining players, designated as *followers*, taking these actions as given in the process of computation of their noncooperative (Nash) equilibria (among themselves). Before announcing their

actions, the leaders would of course anticipate these responses and determine their actions in a way that the final outcome will be most favorable to them (in terms of their objective functions). For a comprehensive treatment of Nash and Stackelberg equilibria for different classes of games, see Başar and Olsder (1982).

We say that a noncooperative game is strictly (or genuinely) *nonzero-sum*, if the sum of the players' objective functions cannot be made zero after appropriate positive scaling and/or translation that do not depend on the players' decision variables. We say that a two-player game is *zero-sum* if the sum of the objective functions of the two players is *zero* or can be made zero by appropriate positive scaling and/or translation that do not depend on the decision variables of the players. On a broader scale (and with a possible abuse of terminology), we can view two-player zero-sum games as constituting a special subclass of two-player nonzero-sum games, and in this case, the Nash equilibrium becomes the *saddle-point equilibrium*. A game is a *finite game* if each player has only a finite number of alternatives, that is, the players pick their actions out of finite sets (action sets); otherwise the game is an *infinite game*; finite games are also known as *matrix games*. An infinite game is said to be a *continuous-kernel game* if the action sets of the players are continua and the players' objective functions are continuous with respect to action variables of all players. A game is said to be *deterministic* if the players' actions uniquely determine the outcome, as captured in the objective functions, whereas if the objective function of at least one player depends on an additional variable (state of nature) with an underlying probability distribution, then we have a *stochastic game*. A game is a *complete information game* if the description of the game (i.e., the players, the objective functions, and the underlying probability distributions (if stochastic)) is common information to all players; otherwise we have an *incomplete information game*. We say that a game is *static* if players have access to only the a priori information (shared by all) and none of the players has access to information on the actions of any of the other players; otherwise what we

have is a *dynamic game*. A game is a *single-act game* if every player acts only once; otherwise the game is *multi-act*. Note that it is possible for a single-act game to be dynamic and for a multi-act game to be static. A dynamic game is said to be a *differential game* if the evolution of the decision process (controlled by the players over time) takes place in continuous time and generally involves a differential equation; if it takes place over a discrete-time horizon, the dynamic game is sometimes called a *discrete-time game*.

In dynamic games, as the game progresses, players acquire information (complete or partial) on past actions of other players and use this information in selecting their own actions (also dictated by the equilibrium solution concept at hand). In finite dynamic games, for example, the progression of a game involves a *tree structure* (also called *extensive form*) where each node is identified with a player along with the time when she acts and branches emanating from a node show the possible moves of that particular player. A player, at any point in time, could generally be at more than one node, which is a situation that arises when the player does not have complete information on the past moves of other players and hence may not know with certainty which a particular node she is at at any particular time. This uncertainty leads to a clustering of nodes into what is called *information sets* for that player. What players decide on within the framework of the extensive form is not their actions but their *strategies*, that is, what action they would take at each information set (in other words, correspondences between their information sets and their allowable actions). They then take specific actions (or actions are executed on their behalf), dictated by the strategies chosen as well as the progression of the game (decision) process along the tree. The equilibrium is then defined in terms of not actions but strategies.

The notion of a *strategy*, as a mapping from the collection of information sets to action sets, extends readily to infinite dynamic games, and hence in both differential games and difference games, Nash equilibria are defined in terms of strategies. Several entries in this *Encyclopedia* discuss such equilibria, for both zero-sum and

nonzero-sum dynamic games, with and without the presence of probabilistic uncertainty. An extensive treatment of dynamic games can also be found in the two-volume *Handbook of Dynamic Game Theory*, whose volume I (Başar and Zaccour 2018a) covers theory and volume II (Başar and Zaccour 2018b) covers various applications.

In the broad scheme of things, game theory, and particularly noncooperative game theory, can be viewed as an extension of two fields, both covered in this *Encyclopedia: Mathematical Programming and Optimal Control Theory*. Any problem in game theory collapses to a problem in one of these disciplines if there is only one player. One-player static games are essentially mathematical programming problems (linear programming or nonlinear programming), and one-player difference or differential games can be viewed as optimal control problems.

Highlights on the History and Evolution of Game Theory

Game Theory has enjoyed over 70 years of scientific development, with the publication of the *Theory of Games and Economic Behavior* by John von Neumann and Oskar Morgenstern (1947) generally acknowledged to *kick start* the field. It has experienced incessant growth in both the number of theoretical results and the scope and variety of applications. As a recognition of the vitality of the field, through 2012, a total of ten Nobel Prizes were given in Economic Sciences for work primarily in game theory, with the first such recognition bestowed in 1994 on John Harsanyi, John Nash, and Reinhard Selten “for their pioneering analysis of equilibria in the theory of noncooperative games.” The second round of Nobel Prizes in game theory went to Robert Aumann and Thomas Schelling in 2005 “for having enhanced our understanding of conflict and cooperation through game-theory analysis.” The third round recognized Leonid Hurwicz, Eric Maskin, and Roger Myerson in 2007 “for having laid the foundations of mechanism design theory.” And the most recent one was in 2012, recognizing

Alvin Roth and Lloyd Shapley “for the theory of stable allocations and the practice of market design.” To this list of highest-level awards related to contributions to game theory, one should also add the 1999 Crafoord Prize (which is the highest prize in Biological Sciences), which went to John Maynard Smith (along with Ernst Mayr and G. Williams) “for developing the concept of evolutionary biology,” where Smith’s recognized contributions had a strong game-theoretic underpinning, through his work on evolutionary games and evolutionary stable equilibrium (Smith and Price 1973; Smith 1974, 1982); this is the topic of one of the entries in this *Encyclopedia* (by Altman). Several other “game theory” entries in the *Encyclopedia* also relate to the contributions of the Nobel Laureates mentioned above.

Even though von Neumann and Morgenstern’s 1944 book is taken as the starting point of the scientific approach to game theory, game-theoretic notions and some isolated key results date back to earlier years and even centuries. Sixteen years earlier, in 1928, John von Neumann himself had resolved completely an open fundamental problem in zero-sum games, that *every finite two-player zero-sum game admits a saddle point in mixed strategies*, which is known as the *Minimax Theorem* (von Neumann 1928) – a result which Emile Borel had conjectured to be false 8 years before. Some early traces of game-theoretic thinking can be seen in the 1802 work (*Considérations sur la théorie mathématique du jeu*) of André-Marie Ampère (1775–1836), who was influenced by the 1777 writings (*Essai d’Arithmétique Morale*) of Georges Louis Buffon (1707–1788).

Which event or writing has really started game-theoretic thinking or approach to decision-making (in law, politics, economics, operations research, engineering, etc.) may be a topic of debate, but what is indisputable is that in (zero-sum) differential games (which is most relevant to control theory), the starting point was the work of Rufus Isaacs in the RAND Corporation in the early 1950s, which remained classified for at least a decade, before being made accessible to a broad readership in 1965 (Isaacs 1965); see also the review Ho (1965) which first introduced

the book to the control community. One of the entries in this *Encyclopedia* (by Bernhard) talks about this history and the theory developed by Isaacs, within the context of pursuit-evasion games, and another entry (by Bernhard) discusses the impact the zero-sum differential game framework has made on robust control design (Başar and Bernhard 1995). Extension of the game-theoretic framework to nonzero-sum differential games with Nash equilibrium as the solution concept was initiated in Starr and Ho (1969) and with Stackelberg equilibrium as the solution concept in Simaan and Cruz (1973). Systematic study of the role information structures play in the existence of such equilibria and their uniqueness or nonuniqueness (termed *informational nonuniqueness*) was carried out in Başar (1974, 1976, 1977).

Related Entries on Game Theory in the Encyclopedia

Several entries in the *Encyclopedia* introduce various sub-areas of game theory and discuss important developments (past and present) in each corresponding area.

The entry ▶ “[Strategic Form Games and Nash Equilibrium](#)” by Ozdaglar introduces the static game framework along with the Nash equilibrium concept, for both finite and infinite games, and discusses the issues of existence and uniqueness as well as efficiency. The entry ▶ “[Dynamic Noncooperative Games](#)” by Castañón focuses on dynamic games, again for both finite and infinite games, and discusses extensive form descriptions of the underlying dynamic decision process, either as trees (in finite games) or difference equations (in discrete-time infinite games). Bernhard, in two entries, discusses continuous-time dynamic games, described by differential equations (so-called differential games), but in the two-person zero-sum case. One of these entries ▶ “[Pursuit-Evasion Games and Zero-Sum Two-Person Differential Games](#)” describes the framework initiated by Isaacs, and several of its extensions for pursuit-evasion games, and the other one ▶ “[Linear Quadratic Zero-Sum Two-Person Differential Games](#)” presents results

on the special case of linear quadratic differential games, with an important application of that framework to robust control and more precisely H^∞ -optimal control.

When the number of players in a nonzero-sum game is countably infinite, or even just sufficiently large, some simplifications arise in the computation and characterization of Nash equilibria. The mathematical framework applicable to this context is provided by *mean field theory*, which is the topic of the entry ▶ [“Mean Field Games”](#) by Caines, who discusses this relatively new theory within the context of stochastic differential games.

Cooperative solution concepts for dynamic games are discussed in the entry ▶ [“Cooperative Solutions to Dynamic Games”](#) by Haurie, who introduces Pareto optimality, the bargaining solution concept by Nash, characteristic functions, core, and C-optimality, and presents some selected results using these concepts. In the entry ▶ [“Evolutionary Games”](#) by Altman, the foundations of, as well as the recent advances in, evolutionary games are presented, along with examples showing their potential as a tool for capturing and modeling interactions in complex systems.

The entry ▶ [“Learning in Games”](#) by Shamma addresses the online computation of Nash equilibrium through an iterative process which takes into account each player’s response to choices made by the remaining players, with built-in learning and adaptation rules; one such scheme that is discussed in the entry is the well-known *fictional play*. Learning is also the topic of the entry ▶ [“Stochastic Games and Learning”](#) by Szajowski, who presents a framework and a set of results using the stochastic games formulation introduced by Shapley in the early 1950s.

The entry ▶ [“Network Games”](#) by Srikant shows how game theory plays an important role in modeling interactions between entities on a network, particularly communication networks, and presents a simple mathematical model to study one such instance, namely, resource allocation in the Internet. How to design a game so as to obtain a desired outcome (as captured by say a Nash equilibrium) is a question central to mechanism design, which is covered in the entry ▶ [“Mechanism Design”](#) by Johari, who discusses

as a specific example the Vickrey-Clarke-Groves (VCG) mechanism.

Two other applications of game theory are to the design of auctions and to security. The entry ▶ [“Auctions”](#) by Hajek addresses the former, discussing general auction theory along with equilibrium strategies and more specifically combinatorial auctions. The latter is addressed in the entry ▶ [“Game Theory for Security”](#) by Alpcan, who discusses how the game-theoretic approach leads to more effective responses to security in complex systems and organizations, with applications to a wide variety of systems and critical infrastructures such as electricity, water, financial services, and communication networks.

Future of Game Theory

The second half of the twentieth century was a golden era for game theory, and all evidence so far in the twenty-first century indicates that the next half century is destined to be a *platinum* era. In all respects game theory is on an upward slope in terms of its vitality, the wealth of topics that fall within its scope, the richness of the conceptual framework it offers, the range of applications, and the challenges it presents to an inquisitive mind.

Graphs for Modeling Networked Interactions

Mehran Mesbahi¹ and Magnus Egerstedt²

¹University of Washington, Seattle, WA, USA

²Georgia Institute of Technology, Atlanta, GA, USA

Abstract

Graphs constitute natural models for networks of interacting agents. This entry introduces graph theoretic formalisms that facilitate analysis and synthesis of coordinated control algorithms over networks.

Keywords

Distributed control · Graph theory · Multi-agent networks

Introduction

Distributed and networked systems are characterized by a set of dynamical units (agents, actors, nodes) that share information with each other in order to achieve a global performance objective using locally available information. Information can typically be shared if agents are within communication or sensing range of each other. It is useful to abstract away the particulars of the underlying information-exchange mechanism and simply say that an link exists between two nodes if they can share information. Such an abstraction is naturally represented in terms of a graph.

A graph is a combinatorial object defined by two constructs: vertices (or nodes) and edges (or links) connecting pairs of distinct vertices. The set of N vertices specified by $V = \{v_1, \dots, v_N\}$ corresponds to the agents, and an edge between vertices v_i and v_j is represented by (v_i, v_j) ; the set of all edges constitutes the edge set E . The *graph* G is thus the pair $G = (V, E)$ and the interpretation is that an edge $(v_i, v_j) \in E$ if information can flow from vertex i to vertex j . If the information exchange is sensor based, and if there is a state x_i associated with vertex i , e.g., its position, then this information is typically relative, i.e., the states are measured relative to each other and the information obtained along the edge is $x_j - x_i$. If, on the other hand, the information is communicated, then the full state information x_i can be transmitted along the edge (v_i, v_j) . The graph abstraction for a network of agents with sensor-based information exchange is illustrated in Fig. 1.

It is often useful to differentiate between scenarios where the information exchange is bidirectional – if agent i can get information from agent j , then agent j can get information from agent i – and when it is not. In the language of graph theory, an undirected graph is one where

Graphs for Modeling Networked Interactions, Fig. 1
A network of agents equipped with omnidirectional range sensors can be viewed as a graph (undirected in this case),

with nodes corresponding to the agents and edges to their pairwise interactions, which are enabled whenever the agents are within a certain distance from each other

$(v_i, v_j) \in E$ implies that $(v_j, v_i) \in E$, while a directed graph is one where such an implication may not hold.

cardinality of the set of edges incident on vertex i . Moreover,

$$a_{ij} = \begin{cases} 1 & \text{if } (v_j, v_i) \in E \\ 0 & \text{otherwise.} \end{cases}$$

Graph-Based Coordination Models

Graphs provide structural insights into how different coordination algorithms behave over a network. A coordination algorithm, or protocol, is an update rule that describes how the node states should evolve over time. To understand such protocols, one needs to connect the interaction dynamics to the underlying graph structure. This connection is facilitated through the common intersection of linear system theory and graph theory, namely, the broad discipline of *algebraic graph theory*, by first associating matrices with graphs. For undirected graphs, the following matrices play a key role:

Degree matrix : $\Delta = \text{Diag}(\deg(v_1), \dots, \deg(v_N))$,

Adjacency matrix : $A = [a_{ij}]$,

where **Diag** denotes a diagonal matrix whose diagonal consists of its argument and $\deg(v_i)$ is the degree of vertex i in the graph, i.e., the

As an example of how these matrices come into play, the so-called *consensus* protocol over scalar states can be compactly written on ensemble form as

$$\dot{x} = -Lx, \quad (1)$$

where $x = [x_1, \dots, x_N]^T$ and L is the *graph Laplacian*:

$$L = \Delta - A.$$

A useful matrix for directed networks is the incidence matrix, obtained by associating an index with each edge in E . We say that $v_i = \text{tail}(e_j)$ if edge e_j starts at node v_i and $v_i = \text{head}(e_j)$ if e_j ends up at v_i , leading to the

Incidence matrix : $D = [d_{ij}]$,

where

$$d_{ij} = \begin{cases} 1 & \text{if } v_i = \text{head}(e_j) \\ -1 & \text{if } v_i = \text{tail}(e_j) \\ 0 & \text{otherwise.} \end{cases}$$

It now follows that for undirected networks, the Laplacian has an equivalent representation as

$$L = DD^T,$$

where D is the incidence matrix associated with an arbitrary orientation (assignment of directions to the edges) of the undirected graph. This in turn implies that for undirected networks, L is a positive semi-definite matrix and that all of its eigenvalues are nonnegative.

If the network is directed, one has to pay attention to the direction in which information is flowing, using the *in-degree* and *out-degree* of the vertices. The out-degree of vertex i is the number of directed edges that originate at i , and similarly the in-degree of node i is the number of directed edges that terminate at node i . A directed graph is *balanced* if the out-degree is equal to the in-degree at every vertex in the graph. And, the graph Laplacian for directed graphs is obtained by only counting information flowing in the correct direction, i.e., if $L = [\ell_{ij}]$, then ℓ_{ii} is the in-degree of vertex i and $\ell_{ij} = -1$ if $i \neq j$ and $(v_j, v_i) \in E$.

As a final note, for both directed and undirected networks, it is possible to associate weights with the edges, $w : E \rightarrow \Upsilon$ where Υ is a set of nonnegative reals or more generally a field, in which case the Laplacian's diagonal elements are the sum of the weights of edges incident to node i and the off-diagonal elements are $-w(v_j, v_i)$ when $(v_j, v_i) \in E$.

Applications

Graph-based coordination has been used in a number of application domains, such as multi-agent robotics, mobile sensor and communication networks, formation control, and biological systems. One way in which the consensus protocol can be generalized is by defining an edge-tension energy $E_{ij}(\|x_i - x_j\|)$ along each edge in the graph, which gives the total energy in the network as

$$E(x) = \sum_{i=1}^N \sum_{j \in N_i} E_{ij}(\|x_i - x_j\|).$$

If the agents update their states in such a way as to reduce the total energy in the system according to a gradient descent scheme, the update law becomes

$$\dot{x} = -\frac{\partial E(x)}{\partial x_i} \Rightarrow \dot{E}(x) = -\left\| \frac{\partial E(x)}{\partial x} \right\|_2^2,$$

which is nonpositive, i.e., the total energy is reduced (or at least not increased) in the network. For undirected networks, the ensemble version of this protocol assumes the form

$$\dot{x} = -L_w(x)x,$$

where the weighted graph Laplacian is

$$L_w(x) = DW(x)D^T,$$

with the weight matrix $W(x) = \text{Diag}(w_1(x), \dots, w_M(x))$. Here M is the total number of edges in the network, and $w_k(x)$ is the weight that corresponds to the k th edge, given an arbitrary ordering of the edges consistent with the incident matrix D . This energy interpretation allows for the synthesis of coordination laws for multi-agent networks with desirable properties, such as $E_{ij}(\|x_i - x_j\|) = (\|x_i - x_j\| - d_{ij})^2$ for making the agents reach the desired interagent distances d_{ij} , as shown in Fig. 2. Other applications where these types of constructions have been used include collision avoidance and connectivity maintenance.

Another set of applications involve graphs as the backbone for mapping inputs to outputs. In this case, group coordination facilitated by information diffusion on the graph has to be balanced with stability and performance criteria for such systems. For example, when an augmented version of the model (1) is subject to a forcing term as

$$\dot{x} = -Lx - D\mu - \nabla f, \quad \dot{\mu} = D^T x,$$

it leads to a (continuous) primal-dual algorithm for minimizing a sum of differentiable functions on $\Re^n$,

Graphs for Modeling Networked Interactions, Fig. 2 Fifteen mobile robots are forming the letter “G” by executing a weighted version of the consensus protocol. (a) Formation control ($t = 0$). (b) Formation control ($t = 5$)

$$J = \sum_{i=1}^n f_i(x),$$

a canonical model in distributed optimization; in this case, ∇f represents the vector of partial derivatives of f_i with respect to the i th coordinate of its argument, for $i = 1, 2, \dots, n$.

One can also consider inputs to the graph by the human operator or adversarial agents; in this case, system theoretic features of the resulting input-output system, such as its controllability, observability, and performance measure, assume an elegant graph theoretic character.

Summary and Future Directions

A number of issues pertaining to graph-based distributed control remain to be resolved. These include how heterogeneous networks, i.e., networks comprising of agents with different capabilities, can be designed, understood, and controlled. A variation to this theme is networks of networks, i.e., networks that are loosely coupled together and that must coordinate at a higher level of abstraction. Other key issues concern how human operators should interact with networked control systems and how network can be endowed with a distributed learning capability.

H₂ Optimal Control

Ben M. Chen

Department of Mechanical and Automation Engineering, Chinese University of Hong Kong, Shatin/Hong Kong, China

Abstract

An optimization-based approach to linear feedback control system design uses the H_2 norm, or energy of the impulse response, to quantify closed-loop performance. In this entry, an overview of state-space methods for solving H_2 optimal control problems via Riccati equations and matrix inequalities is presented in a continuous-time setting. Both regular and singular problems are considered. Connections to so-called LQR and LQG control problems are also described.

Keywords

Feedback control · H_2 control · Linear matrix inequalities · Linear systems · Riccati equations · State-space methods

Introduction

Modern multivariable control theory based on state-space models is able to handle multi-feedback-loop designs, with the added benefit

that design methods derived from it are amenable to computer implementation. Indeed, over the last five decades, a number of multivariable analysis and design have been developed using the state-space description of systems. Of these design tools, H_2 optimal control problems involve minimizing the H_2 norm of the closed-loop transfer function from exogenous disturbance signals to a pertinent controlled output signals of a given plane by appropriate use of an internally stabilizing feedback controller. It was not until the 1990s that a complete solution to the general H_2 optimal control problem began to emerge. To elaborate on this, let us concentrate our discussion on H_2 optimal control for a continuous-time system Σ expressed in the following state-space form:

$$\dot{x} = Ax + Bu + Ew \quad (1)$$

$$y = C_1x + D_{11}u + D_{1w} \quad (2)$$

$$z = C_2x + D_{2u} + D_{2w} \quad (3)$$

where x is the state variable; u is the control input; w is the exogenous disturbance input; y is the measurement output; and z is the controlled output. The system Σ is typically an augmented or generalized plant model including weighting functions that reflect design requirements. The H_2 optimal control problem is to find an appropriate control law, relating the control input u to the measured output y , such that when it is applied to the given plant in Eqs. (1), (2) and (3), the resulting closed-loop system is internally

stable and the H_2 norm of the resulting closed-loop transfer matrix from the disturbance input w to the controlled output z , denoted by $T_{zw}(s)$, is minimized. For a stable transfer matrix $T_{zw}(s)$, the H_2 norm is defined as

$$\|T_{zw}\|_2 = \left(\frac{1}{2\pi} \operatorname{trace} \left[\int_{-\infty}^{\infty} T_{zw}(j\omega) T_{zw}^H(j\omega) d\omega \right] \right)^{\frac{1}{2}} \quad (4)$$

where T_{zw}^H is the conjugate transpose of T_{zw} . Note that the H_2 norm is equal to the energy of the impulse response associated with $T_{zw}(s)$ and this is finite only if the direct feedthrough term of the transfer matrix is zero.

It is standard to make the following assumptions on the problem data: $D_{11} = 0$; $D_{22} = 0$; (A, B) is stabilizable; (A, C_1) is detectable. The last two assumptions are necessary for the existence of an internally stabilizing control law. The first assumption can be made without loss of generality via a constant loop transformation. Finally, either the assumption $D_{22} = 0$ can be achieved by a pre-static feedback law or the problem does not yield a solution that has finite H_2 closed-loop norm.

There are two main groups into which all H_2 optimal control problems can be divided. The first group, referred to as regular H_2 optimal control problems, consists of those problems for which the given plant satisfies two additional assumptions:

1. the subsystem from the control input to the controlled output, i.e., (A, B, C_2, D_2) , has no invariant zeros on the imaginary axis, and its direct feedthrough matrix, D_2 , is injective (i.e., it is tall and of full rank); and
2. the subsystem from the exogenous disturbance to the measurement output, i.e., (A, E, C_1, D_1) , has no invariant zeros on the imaginary axis, and its direct feedthrough matrix, D_1 , is surjective (i.e., it is fat and of full rank).

Assumption 1 implies that (A, B, C_2, D_2) is left invertible with no infinite zero, and Assumption 2 implies that (A, E, C_1, D_1) is right invertible with no infinite zero. The second, referred to as

singular H_2 optimal control problems, consists of those which are not regular.

Most of the research in the literature was expended on regular problems. Also, most of the available textbooks and review articles, see, for example, Anderson and Moore (1989), Bryson and Ho (1975), Fleming and Rishel (1975), Kailath (1974), Kwakernaak and Sivan (1972), Lewis (1986), and Zhou et al. (1996), to name a few, cover predominantly only a subset of regular problems. The singular H_2 control problem with state feedback was studied in Geerts (1989) and Willems et al. (1986). Using different classes of state and measurement feedback control laws, Stoorvogel et al. (1993) studied the general H_2 optimal control problems for the first time. In particular, necessary and sufficient conditions are provided therein for the existence of a solution in the case of state feedback control and in the case of measurement feedback control. Following this, Trentelman and Stoorvogel (1995) explored necessary and sufficient conditions for the existence of an H_2 optimal controller within the context of discrete-time and sampled-data systems. At the same time, Chen et al. (1993) and Chen et al. (1994a) provided a thorough treatment of the H_2 optimal control problem with state feedback controllers. This includes a parameterization and construction of the set of all H_2 optimal controllers and the associated sets of H_2 optimal fixed modes and H_2 optimal fixed decoupling zeros. Also, they provided a computationally feasible design algorithm for selecting an H_2 optimal state feedback controller that places the closed-loop poles at desired locations whenever possible. Furthermore, Chen and Saberi (1993) and Chen et al. (1996) developed the necessary and sufficient conditions for the uniqueness of an H_2 optimal controller. Interested readers are referred to the textbook (Saberi et al. 1995) for a detailed treatment of H_2 optimal control problems in their full generality.

Regular Case

Solving regular H_2 optimal control problems is relatively straightforward. In the case that all of

the state variables of the given plant are available for feedback, i.e., $y = x$, and Assumption 1 holds, the corresponding H_2 optimal control problem can be solved in terms of the unique positive semi-definite stabilizing solution $P \geq 0$ of the following algebraic Riccati equation:

$$A^T P + P A + C_2^T C_2 - (P B + C_2^T D_2)(D_2^T D_2)^{-1} (D_2^T C_2 + B^T P) = 0 \quad (5)$$

The H_2 optimal state feedback law is given by

$$u = Fx = -(D_2^T D_2)^{-1} (D_2^T C_2 + B^T P) x \quad (6)$$

and the resulting closed-loop transfer matrix from w to z , $T_{zw}(s)$, has the following property:

$$\|T_{zw}\|_2 = \sqrt{\text{trace}(E^T P E)} \quad (7)$$

Note that the H_2 optimal state feedback control law is generally nonunique. A trivial example is the case when $E = 0$, whereby every stabilizing control law is an optimal solution. It is also interesting to note that the closed-loop system comprising the given plant with $y = x$ and the state feedback control law of Eq. (6) has poles at all the stable invariant zeros and all the mirror images of the unstable invariant zeros of (A, B, C_2, D_2) together with some other fixed locations in the left half complex plane. More detailed results about the optimal fixed modes and fixed decoupling zeros for general H_2 optimal control can be found in Chen et al. (1993).

It can be shown that the well-known linear quadratic regulation (LQR) problem can be reformulated as a regular H_2 optimal control problem. For a given plant

$$\dot{x} = Ax + Bu, \quad x(0) = X_0 \quad (8)$$

with (A, B) being stabilizable, the LQR problem is to find a control law $u = Fx$ such that the following performance index is minimized:

$$J = \int_0^\infty (x^T Q_\star x + u^T R_\star u) dt, \quad (9)$$

where $R_\star > 0$ and $Q_\star \geq 0$ with $(A, Q_\star^{\frac{1}{2}})$ being detectable. The LQR problem is equivalent to finding a static state feedback H_2 optimal control law for the following auxiliary plant Σ_{LQR} :

$$\dot{x} = Ax + Bu + X_0 w \quad (10)$$

$$y = x \quad (11)$$

$$z = \begin{pmatrix} 0 \\ Q_\star^{\frac{1}{2}} \end{pmatrix} x + \begin{pmatrix} R_\star^{\frac{1}{2}} \\ 0 \end{pmatrix} u \quad (12)$$

For the measurement feedback case with both Assumptions 1 and 2 being satisfied, the corresponding H_2 optimal control problem can be solved by finding a positive semi-definite stabilizing solution $P \geq 0$ for the Riccati equation given in Eq. (5) and a positive semi-definite stabilizing solution $Q \geq 0$ for the following Riccati equation:

$$Q A^T + A Q + E E^T - (Q C_1^T + E D_1^T) (D_1 D_1^T)^{-1} (D_1 E^T + C_1 Q) = 0 \quad (13)$$

The H_2 optimal measurement feedback law is given by

$$\dot{v} = (A + B F + K C_1) v - K y, \quad u = F x \quad (14)$$

where F is as given in Eq. (6) and

$$K = -(Q C_1^T + E D_1^T) (D_1 D_1^T)^{-1} \quad (15)$$

In fact, such an optimal control law is unique, and the resulting closed-loop transfer matrix from w to z , $T_{zw}(s)$, has the following property:

$$\|T_{zw}\|_2 = \left\{ \text{trace}(E^T P E) + \text{trace} \left[\left(A^T P + P A + C_2^T C_2 \right) Q \right] \right\}^{\frac{1}{2}} \quad (16)$$

Similarly, consider the standard LQG problem for the following system

$$\dot{x} = Ax + Bu + G_\star d \quad (17)$$

$$y = Cx + N_\star n, \quad N_\star > 0 \quad (18)$$

$$z = \begin{pmatrix} H_\star x \\ R_\star u \end{pmatrix}, \quad R_\star > 0, \quad w = \begin{pmatrix} d \\ n \end{pmatrix} \quad (19)$$

where x is the state, u is the control, d and n are white noises with identity covariance, and y is the measurement output. It is assumed that (A, B) is stabilizable and (A, C) is detectable. The control objective is to design an appropriate control law that minimizes the expectation of $|z|^2$. Such an LQG problem can be solved via the H_2 optimal control problem for the following auxiliary system Σ_{LQG} , see Doyle (1983):

$$\dot{x} = Ax + Bu + [G_\star \ 0]w \quad (20)$$

$$y = Cx + [0 \ N_\star]w \quad (21)$$

$$z = \begin{pmatrix} H_\star \\ 0 \end{pmatrix} x + \begin{pmatrix} 0 \\ R_\star \end{pmatrix} u \quad (22)$$

H_2 optimal control problem for discrete-time systems can be solved in a similar way via the corresponding discrete-time algebraic Riccati equations. It is worth noting that many works can be found in the literature that deal with solutions to discrete-time algebraic Riccati equations related to optimal control problems; see, for example, Kucera (1972), Pappas et al. (1980), and Silverman (1976), to name a few. It is proven in Chen et al. (1994b) that solutions to the discrete- and continuous-time algebraic Riccati equations for optimal control problems can be unified. More specifically, the solution to a discrete-time Riccati equation can be done through solving an equivalent continuous-time one and vice versa.

Singular Case

As in the previous section, only the key procedure in solving the singular H_2 -optimization problem for continuous-time systems is addressed. For the singular problem, it is generally not possible to obtain an optimal solution, except for some situations when the given plant satisfies certain geometric constraints, see, e.g., Chen et al. (1993)

and Stoorvogel et al. (1993). It is more feasible to find a suboptimal control law for the singular problem, i.e., to find an appropriate control law such that the H_2 norm of the resulting closed-loop transfer matrix from w to z can be made arbitrarily close to the best possible performance. The procedure given below is to transform the original problem into an H_2 almost disturbance decoupling problem; see Stoorvogel (1992) and Stoorvogel et al. (1993).

Consider the given plant in Eqs. (1), (2) and (3) with Assumption 1 and/or Assumption 2 not satisfied. First, find the largest solution $P \geq 0$ for the following linear matrix inequality

$$F(P) = \begin{pmatrix} A^T P + P A + C_2^T C_2 & P B + C_2^T D_2 \\ B^T P + D_2^T C_2 & D_2^T D_2 \end{pmatrix} \geq 0 \quad (23)$$

and find the largest solution $Q \geq 0$ for

$$G(Q) = \begin{pmatrix} A Q + Q A^T + E E^T & Q C_1^T + E D_1^T \\ C_1 Q + D_1 E^T & D_1 D_1^T \end{pmatrix} \geq 0 \quad (24)$$

Note that by decomposing the quadruples (A, B, C_2, D_2) and (A, E, C_1, D_1) into various subsystems in accordance with their structural properties, solutions to the above linear matrix inequalities can be obtained by solving a Riccati equation similar to those in Eq. (5) or Eq. (13) for the regular case. In fact, for the regular problem, the largest solution $P \geq 0$ for Eq. (23) and the stabilizing solution $P \geq 0$ for Eq. (5) are identical. Similarly, the largest solution $Q \geq 0$ for Eq. (24) and the stabilizing solution $Q \geq 0$ for Eq. (13) are also the same. Interested readers are referred to Stoorvogel et al. (1993) for more details or to Chen et al. (2004) for a more systematic treatment on the structural decomposition of linear systems and its connection to the solutions of the linear matrix inequalities.

It can be shown that the best achievable H_2 norm of the closed-loop transfer matrix from w to z , i.e., the best possible performance over all internally stabilizing control laws, is given by

$$\gamma_2^* = \left\{ \text{trace}(E^T P E) + \text{trace} \left[\left(A^T P + P A + C_2^T C_2 \right) Q \right] \right\}^{\frac{1}{2}} \quad (25)$$

Next, partition

$$F(P) = \begin{pmatrix} C_P^T \\ D_P^T \end{pmatrix} (C_P \ D_P) \quad \text{and} \quad G(Q) = \begin{pmatrix} E_Q \\ D_Q \end{pmatrix} (E_Q^T \ D_Q^T) \quad (26)$$

where $[C_P \ D_P]$ and $[E_Q^T \ D_Q^T]$ are of maximal rank, and then define an auxiliary system Σ_{PQ} :

$$\dot{x}_{PQ} = A x_{PQ} + B u + E_Q w_{PQ} \quad (27)$$

$$y = C_1 x_{PQ} + D_Q w_{PQ} \quad (28)$$

$$z_{PQ} = C_P x_{PQ} + D_P u \quad (29)$$

It can be shown that the quadruple (A, B, C_P, D_P) is right invertible and has no invariant zeros in the open right-half complex plane and the quadruple (A, E_Q, C_1, D_Q) is left invertible and has no invariant zeros in the open right-half complex plane. It can also be shown that there exists an appropriate control law such that when it is applied to Σ_{PQ} , the resulting closed-loop system is internally stable and the H_2 norm of the closed-loop transfer matrix from w_{PQ} to z_{PQ} can be made arbitrarily small. Equivalently, H_2 almost disturbance decoupling problem for Σ_{PQ} is solvable.

More importantly, it can further be shown that if an appropriate control law that solves the H_2 almost disturbance decoupling problem for Σ_{PQ} , then it solves the H_2 suboptimal problem for Σ . As such, the solution to the singular H_2 control problem for Σ can be done by finding a solution to the H_2 almost disturbance decoupling problem for Σ_{PQ} . There are vast results available in the literature dealing with disturbance decoupling problems. More detailed treatments can be found in Saberi et al. (1995).

Conclusion

This entry considers the basic solutions to H_2 optimal control problems for continuous-time systems. Both the regular problem and the general singular problem are presented. Readers interested in more details are referred to Saberi et al. (1995) and the references therein for the complete treatment of H_2 optimal control problems and to Chapter 10 of Chen et al. (2004) for the unification and differentiation of H_2 control, H_∞ control, and disturbance decoupling control problems. H_2 optimal control is a mature area and has a long history. Possible future research includes issues on how to effectively utilize the theory in solving real-life problems.

H-Infinity Control

Keith Glover
Department of Engineering, University of
Cambridge, Cambridge, UK

Abstract

The area of robust control, where the performance of a feedback system is designed to be robust to uncertainty in the plant being controlled, has received much attention since

the 1980s. System analysis and controller synthesis based on the H-infinity norm has been central to progress in this area. This article outlines how the control law that minimizes the H-infinity norm of the closed-loop system can be derived. Connections to other problems, such as game theory and risk-sensitive control, are discussed and finally appropriate problem formulations to produce “good” controllers using this methodology are outlined.

Keywords

Loop-shaping · Robust control · Robust stability

Introduction

The $\mathcal{H}_\infty$ -norm probably first entered the study of robust control with the observations made by Zames (1981) in the considering optimal sensitivity. The so-called $\mathcal{H}_\infty$ methods were subsequently developed and are now routinely available to control engineers. In this entry we consider the $\mathcal{H}_\infty$ methods for control, and for simplicity of exposition, we will restrict our attention to linear, time-invariant, finite dimensional, continuous-time systems. Such systems can be represented by their transfer function matrix, $G(s)$, which will then be a rational function of s . Although the Hardy Space, $\mathcal{H}_\infty$, also includes nonrational functions, a rational $G(s)$ is in $\mathcal{H}_\infty$ if and only if it is proper and all its poles are in the open left half plane, in which case the $\mathcal{H}_\infty$ -norm is defined as:

$$\|G(s)\|_\infty = \sup_{\text{Res} > 0} \sigma_{\max}(G(s)) = \sup_{-\infty < \omega < \infty} \sigma_{\max}(G(j\omega))$$

(where $\sigma_{\max}$ denotes the largest singular value). Hence for a single input/single output system with transfer function, $g(s)$, its $\mathcal{H}_\infty$ -norm, $\|g(s)\|_\infty$ gives the maximum value of $|g(j\omega)|$ and hence the maximum amplification of sinusoidal signals by a system with this transfer function. In the multi-input/multi-output case a similar result holds regarding the system

amplification of a vector of sinusoids. There is now a good collection of graduate level textbooks that cover the area in some detail from a variety of approaches, and these are listed in the Recommended Reading section and the references in this article are generally to these texts rather than to the original journal papers.

Consider a system with transfer function, $G(s)$, input vector, $u(t) \in \mathcal{L}_2(0, \infty)$ and an output vector, $y(t)$, whose Laplace transforms are given by $\bar{u}(s)$ and $\bar{y}(s)$. Such a system will have a state space realization,

$$\dot{x}(t) = Ax(t) + Bu(t), \quad y(t) = Cx(t) + Du(t)$$

giving $G(s) = D + C(sI - A)^{-1}B$, which we also denote

$$G(s) = \left[\begin{array}{c|c} A & B \\ \hline C & D \end{array} \right],$$

and hence $\bar{y}(s) = G(s)\bar{u}(s)$ if $x(0) = 0$.

There are two main reasons for using the $\mathcal{H}_\infty$ -norm. Firstly in representing the system gain for input signals $u(t) \in \mathcal{L}_2(0, \infty)$ or equivalently $\bar{u}(j\omega) \in \mathcal{L}_2(-\infty, \infty)$, with corresponding norm $\|u\|_2^2 = \int_0^\infty u(t)^* u(t) dt$ (where x^* denotes the conjugate transpose of the vector x (or a matrix)). With these input and output spaces the induced norm of the system is easily shown to be the $\mathcal{H}_\infty$ -norm of $G(s)$, and in particular,

$$\|y\|_2 \leq \|G(s)\|_\infty \|u\|_2$$

Hence in a control context the $\mathcal{H}_\infty$ -norm can give a measure of the gain, for example, from disturbances to the resulting errors. In the interconnection of systems, the property that $\|P(s)Q(s)\|_\infty \leq \|P(s)\|_\infty \|Q(s)\|_\infty$ is often useful.

The second reason for using the $\mathcal{H}_\infty$ -norm is in representing uncertainty in the plant being controlled, e.g., the nominal plant is $P_o(s)$ but the actual plant is $P(s) = P_o(s) + \Delta(s)$ where $\|\Delta(s)\|_\infty \leq \delta$.

A typical control design problem is given in Fig. 1, i.e.,

H-Infinity Control, Fig. 1 Lower linear fractional transformation: feedback system

$$\begin{bmatrix} \bar{z} \\ \bar{y} \end{bmatrix} = P \begin{bmatrix} \bar{w} \\ \bar{u} \end{bmatrix} = \begin{bmatrix} P_{11}\bar{w} + P_{12}\bar{u} \\ P_{21}\bar{w} + P_{22}\bar{u} \end{bmatrix}$$

$$\bar{u} = K\bar{y}$$

$$\Rightarrow \bar{y} = (I - P_{22}K)^{-1}P_{21}\bar{w},$$

$$\bar{u} = K(I - P_{22}K)^{-1}P_{21}\bar{w}$$

$$\bar{z} = \left(P_{11} + P_{12}K(I - P_{22}K)^{-1}P_{21} \right) \bar{w}$$

$$=: \mathcal{F}_l(P, K)\bar{w} =: T_{z \leftarrow w}\bar{w}$$

where $\mathcal{F}_l(P, K)$ denotes the lower Linear Fractional Transformation (LFT) with connection around the lower terminals of P as in Fig. 1.

The standard $\mathcal{H}_\infty$ -control synthesis problem is to find a controller with transfer function, K , that

stabilizes the closed-loop system in Fig. 1 and minimizes $\|\mathcal{F}_l(P, K)\|_\infty$.

That is, the controller is designed to minimize the worst-case effect of the disturbance w on the output/error signal z as measured by the $\mathcal{L}_2$ norm of the signals. This article will describe the solution to this problem.

Robust Stability

Before we describe the solution to the synthesis problem, consider the problem of the robust stability of an uncertain plant with a feedback controller. Suppose the plant is given by the upper

H-Infinity Control, Fig. 2 Upper linear fractional transformation

LFT, $\mathcal{F}_u(P, \Delta)$ with $\|\Delta\|_\infty \leq 1/\gamma$ as illustrated in Fig. 2,

$$\bar{y} = \mathcal{F}_u(P, \Delta)\bar{u}, \quad (1)$$

$$\text{where } \mathcal{F}_u(P, K) := P_{22} + P_{21}\Delta(I - P_{11}\Delta)^{-1}P_{12} \quad (2)$$

The *small gain theorem* then states that the feedback system of Fig. 3 will be stable for all such Δ if the feedback connection of P_{22} and K is stable and $\|\mathcal{F}_l(P, K)\|_\infty < \gamma$. This robust stability result is valid if P and Δ are both stable; more care is required when either or both are unstable but with such care a similar result is true.

Let us consider a couple of examples. First suppose that the uncertainty is represented as output multiplicative uncertainty,

$$P_\Delta = (I + W_1\Delta W_2)P_o = \mathcal{F}_u\left(\begin{bmatrix} 0 & W_2P_o \\ W_1 & P_o \end{bmatrix}, \Delta\right)$$

with robust stability test given by

$$\begin{aligned} & \|\mathcal{F}_l\left(\begin{bmatrix} 0 & W_2P_o \\ W_1 & P_o \end{bmatrix}, K\right)\|_\infty \\ &= \|W_2P_oK(I - P_oK)^{-1}W_1\|_\infty < \gamma \end{aligned}$$

As a second example consider the plants $P_\Delta = (\tilde{M} + \Delta_M)^{-1}(\tilde{N} + \Delta_N)$, with $\Delta = \begin{bmatrix} \Delta_N & \Delta_M \end{bmatrix}$ and $\|\Delta\|_\infty \leq 1/\gamma$. Here $P_o = \tilde{M}^{-1}\tilde{N}$ is a left coprime factorization of the nominal plant and the plants P_Δ are represented by perturbations

H-Infinity Control, Fig. 3 Feedback system with plant uncertainty

to these coprime factors. In this case $P_\Delta = \mathcal{F}_u(P, \Delta)$, where

$$P = \begin{bmatrix} \begin{bmatrix} 0 \\ -\tilde{M}^{-1} \end{bmatrix} \\ \tilde{M}^{-1} \end{bmatrix} \begin{bmatrix} I \\ -\tilde{M}^{-1}\tilde{N} \end{bmatrix}$$

and the robust stability test will be

$$\|\mathcal{F}_l(P, K)\|_\infty = \left\| \begin{bmatrix} K \\ -I \end{bmatrix} (I - P_oK)^{-1}\tilde{M}^{-1} \right\|_\infty < \gamma$$

This is related to plant perturbations in the gap metric (see Vinnicombe 2001). It is therefore observed that the robust stability test for these useful representations of uncertain plants is given by an $\mathcal{H}_\infty$ -norm test just as in the controller synthesis problem.

Derivation of the $\mathcal{H}_\infty$ -Control Law

In this section we present a solution to the $\mathcal{H}_\infty$ -control problem and give some interpretations of the solution. The approach presented is as in by Doyle et al. (1989); see also Zhou et al. (1996). We will make some simplifying structural assumptions to make the formulae less complex

and will *not* state the required assumptions on rank, stabilizability, and detectability. Let the system in Fig. 1 be described by the equations:

$$\dot{x}(t) = Ax(t) + B_1w(t) + B_2u(t) \quad (3)$$

$$z(t) = C_1x(t) + D_{12}u(t) \quad (4)$$

$$y(t) = C_2x(t) + D_{21}w(t) \quad (5)$$

i.e., in Fig. 1

$$P = \left[\begin{array}{c|cc} A & B_1 & B_2 \\ \hline C_1 & 0 & D_{12} \\ C_2 & D_{21} & 0 \end{array} \right]$$

where we also assume, with little loss of generality, that $D_{12}^*D_{12} = I$, $D_{21}D_{21}^* = I$, $D_{12}^*C_1 = 0$ and $B_1D_{21}^* = 0$. Since we wish to have $\|T_{z \leftarrow w}\|_\infty < \gamma$, we need to find u such that

$$\|z\|_2^2 - \gamma^2\|w\|_2^2 < 0 \text{ for all } w \neq 0 \in \mathcal{L}_2(0, \infty).$$

We could consider w to be an adversary trying to make this expression positive, while u has to ensure that it always remains negative in spite of the malicious intentions of w , as in a noncooperative game. Suppose that there exists a solution, X_∞ , to the Algebraic Riccati Equation (ARE),

$$A^*X_\infty + X_\infty A + C_1^*C_1 + X_\infty(\gamma^{-2}B_1B_1^* - B_2B_2^*)X_\infty = 0 \quad (6)$$

with $X_\infty \geq 0$ and $A + (\gamma^{-2}B_1B_1^* - B_2B_2^*)X_\infty$ a stable “A-matrix.” A simple substitution then gives that

$$\begin{aligned} \frac{d}{dt}(x(t)^*X_\infty x(t)) &= -z^*z + \gamma^2w^*w \\ &\quad + v^*v - \gamma^2r^*r \end{aligned}$$

where

$$v := u + B_2^*X_\infty x, \quad r := w - \gamma^{-2}B_1^*X_\infty x.$$

Now let $x(0) = 0$ and assuming stability so that $x(\infty) = 0$, then integrating from 0 to ∞ gives

$$\|z\|_2^2 - \gamma^2\|w\|_2^2 = \|v\|_2^2 - \gamma^2\|r\|_2^2 \quad (7)$$

If the state is available to u , then the control law $u = -B_2^*X_\infty x$ gives $v = 0$ and $\|z\|_2^2 - \gamma^2\|w\|_2^2 < 0$ for all $w \neq 0$. It can be shown that (6) has a solution if there exists a controller such that $\|F_l(P, K)\|_\infty < \gamma$. In addition since transposing a system does not change its $\mathcal{H}_\infty$ -norm, the following dual ARE will also have a solution, $Y_\infty \geq 0$,

$$\begin{aligned} AY_\infty + Y_\infty A^* + B_1B_1^* \\ + Y_\infty(\gamma^{-2}C_1^*C_1 - C_2^*C_2)Y_\infty = 0 \end{aligned} \quad (8)$$

To obtain a solution to the output feedback case, note that (7) implies that $\|z\|_2^2 < \gamma^2\|w\|_2^2$ if and only if $\|v\|_2^2 < \gamma^2\|r\|_2^2$ and $\bar{v} = F_l(P_{\text{tmp}}, K)\bar{r}$ where

$$\begin{bmatrix} \bar{v} \\ \bar{y} \end{bmatrix} = P_{\text{tmp}} \begin{bmatrix} \bar{r} \\ \bar{u} \end{bmatrix},$$

and

$$P_{\text{tmp}} = \left[\begin{array}{c|cc} A + \gamma^{-2}B_1B_1^*X_\infty & B_1 & B_2 \\ \hline B_2^*X_\infty & 0 & I \\ C_2 & D_{21} & 0 \end{array} \right]$$

The special structure of this problem enables a solution to be derived in much the same way as the dual of the state feedback problem. The corresponding ARE will have a solution $Y_{\text{tmp}} = (I - \gamma^{-2}Y_\infty X_\infty)^{-1}Y_\infty \geq 0$ if and only if the spectral radius $\rho(Y_\infty X_\infty) < \gamma^2$.

The above outline, supported by significant technical detail and assumptions, will therefore demonstrate that there exists a stabilizing controller, $K(s)$, such that the system described by (3–5) satisfies $\|T_{z \leftarrow w}\|_\infty < \gamma$ if and only if there exist stabilizing solutions to the AREs in (6) and (8) such that

$$X_\infty \geq 0, \quad Y_\infty \geq 0, \quad \rho(Y_\infty X_\infty) < \gamma^2 \quad (9)$$

The state equations for the resulting controller can be written as

$$\begin{aligned}\dot{\hat{x}} &= A\hat{x} + B_1\hat{w}_{\text{worst}} + B_2u + Z_\infty L_\infty (C_2\hat{x} - y) \\ u &= F_\infty\hat{x}, \quad \hat{w}_{\text{worst}} = \gamma^{-2}B_1^*X_\infty\hat{x} \\ F_\infty &:= -B_2^*X_\infty, \quad L_\infty := -Y_\infty C_2^*, \\ Z_\infty &:= (I - \gamma^{-2}Y_\infty X_\infty)^{-1}\end{aligned}$$

giving feedback from a state estimator in the presence of an estimate of the worst-case disturbance.

As $\gamma \rightarrow \infty$ the standard LQG controller is obtained with state feedback of a state estimate obtained from a Kalman filter. In contrast to the LQG problem, the controller depends on the value of γ , and if this is chosen to be too small, then one of the conditions in (9) will be violated. In order to determine the minimum achievable value of γ , a bisection search over γ can be performed checking (9) for each candidate value of γ .

In the limit as $\gamma \rightarrow \gamma_{\text{opt}}$ (its minimum value), a variety of situations can arise and the formulae given here may become ill-conditioned. Typically achieving γ_{opt} is more of an interesting and sometimes challenging mathematical exercise rather than a control system requirement.

This control problem does not have a unique solution, and all solutions can be characterized by an LFT form such as $K = \mathcal{F}_l(M, Q)$ where $Q \in \mathcal{H}_\infty$ with $\|Q\|_\infty < 1$, the present solution is sometimes referred to as the ‘‘central solution’’ obtained with $Q = 0$.

Relations for Other Solution Methods and Problem Formulations

The $\mathcal{H}_\infty$ -control problem has been shown to be related to an extraordinarily wide variety of mathematical techniques and to other problem areas, and investigations of these connections have been most fruitful. Earlier approaches (see Francis 1988) firstly used the characterization of all stabilizing controllers of Youla et al. (see Vidyasagar 1985) which shows that all stable closed-loop systems can be written as

$$\mathcal{F}_l(P, K) = T_1 + T_2 Q T_3, \quad \text{where } Q \in \mathcal{H}_\infty$$

and then solved the model matching problem $\inf_{Q \in \mathcal{H}_\infty} \|T_1 + T_2 Q T_3\|_\infty$. This model matching problem is related to interpolation theory and resulted in a productive interaction with the operator theory. One solution method reduces this problem to J-spectral factorisation problems (where $J = \begin{bmatrix} I & 0 \\ 0 & -I \end{bmatrix}$) and generates state-space solutions to these problems (Kimura 1997).

The derivation above clearly demonstrates relations to noncooperative differential games, and this is fully developed in Başar and Bernhard (1995) and Green and Limebeer (1995).

The model matching problem is clearly a convex optimization problem. The solution of linear matrix inequalities can give effective methods for solving certain convex optimization problems (e.g., calculating the $\mathcal{H}_\infty$ norm using the bounded real lemma) and can be exploited in the $\mathcal{H}_\infty$ -control problem. See Boyd and Barratt (1991) for a variety of results on convex optimization and control and Dullerud and Paganini (2000) for this approach in robust control.

As noted above there is a family of solutions to the $\mathcal{H}_\infty$ -control problem. The central solution in fact minimizes the entropy integral given by

$$\begin{aligned}I(T_{z \leftarrow w}; \gamma) &:= -\frac{\gamma^2}{2\pi} \int_{-\infty}^{\infty} \ln \\ &\quad \left| \det(I - \gamma^{-2} T_{z \leftarrow w}(j\omega)^* T_{z \leftarrow w}(j\omega)) \right| d\omega\end{aligned}\quad (10)$$

It can be seen that this criterion will penalize the singular values of $T_{z \leftarrow w}(j\omega)$ from being close to γ for a large range of frequencies.

One of the more surprising connections is with the risk-sensitive stochastic control problem (Whittle 1990) where w is assumed to be Gaussian white noise and it is desired to minimize

$$J_T(\gamma) := \frac{\gamma^2}{T} \ln \mathbf{E} \left\{ e^{\frac{1}{2}\gamma^{-2} V_T} \right\} \quad (11)$$

$$\text{where } V_T := \int_{-T}^T z(t)^* z(t) dt \quad (12)$$

The situation with $\gamma^2 > 0$ corresponds to the risk averse controller since large values of V_T

are heavily penalized by the exponential function. It can be shown that if $\|T_{z \leftarrow w}\|_\infty < \gamma$, then

$$\lim_{T \rightarrow \infty} J_T(\gamma) = I(T_{z \leftarrow w}; \gamma)$$

and hence the central controller minimizes both the entropy integral and the risk-sensitive cost function. When γ is chosen to be too small, Whittle refers to the controller having a “neurotic breakdown” because the cost will be infinite for all possible control laws! If in (11) we set $\gamma^2 = -\theta^{-1}$, then the entropy minimizing controller will have $\theta < 0$ and will be risk-averse. The risk neutral controller is when $\theta \rightarrow 0$, $\gamma \rightarrow \infty$ and gives the standard LQG case. If $\theta > 0$, then the controller will be risk-seeking, believing that large variance will be in its favor.

Controller Design with $\mathcal{H}_\infty$ Optimization

The above solutions to the $\mathcal{H}_\infty$ mathematical problem do not give guidance on how to set up a problem to give a “good” control system design. The problem formulation typically involves identifying frequency-dependent weighting matrices to characterize the disturbances, w , and the relative importance of the errors, z (see Skogestad and Postlethwaite 1996). The choice of weights should also incorporate system uncertainty to obtain a robust controller.

One approach that combines both closed-loop system gain and system uncertainty is called $\mathcal{H}_\infty$ *loop-shaping* where the desired closed-loop behavior is determined by the design of the loop-shape using pre- and post-compensators and the system uncertainty is represented in the gap metric (see Vinnicombe 2001). This makes classical criteria such as low frequency tracking error, bandwidth, and high-frequency roll-off all easily incorporated. In this framework the performance and robustness measures are very well matched to each other. Such an approach has been successfully exploited in a number of practical examples (e.g., Hyde (1995) for flight control taken through to successful flight tests). Standard

control design software packages now routinely have $\mathcal{H}_\infty$ -control design modules.

Summary and Future Directions

We have outlined the derivation of $\mathcal{H}_\infty$ controllers with straightforward assumptions that nevertheless exhibit most of the features of linear time-invariant systems without such assumptions and for which routine design software is now available. Connections to a surprisingly large range of other problems are also discussed.

Generalizations to more general cases such as time-varying and nonlinear systems, where the norm is interpreted as the induced norm of the system in $\mathcal{L}_2$, can be derived although the computational aspects are no longer routine. For the problems of robust control, there are necessarily continuing efforts to match the mathematical representation of system uncertainty and system performance to the physical system requirements and to have such representations amenable to analysis and computation.

History of Adaptive Control

Karl Åström

Department of Automatic Control, Lund University, Lund, Sweden

Abstract

This entry gives an overview of the development of adaptive control, starting with the early efforts in flight and process control. Two popular schemes, the model reference adaptive controller and the self-tuning regulator, are described with a thumbnail overview of theory and applications. There is currently a resurgence in adaptive flight control as well as in other applications. Some reflections on future development are also given.

Keywords

Adaptive control · Auto-tuning · Flight control · History · Model reference adaptive control · Process control · Robustness · Self-tuning regulators · Stability

Introduction

In everyday language, *to adapt* means to change a behavior to conform to new circumstances, for example, when the pupil area changes to accommodate variations in ambient light. The distinction between adaptation and conventional feedback is subtle because feedback also attempts to reduce the effects of disturbances and plant uncertainty. Typical examples are *adaptive optics* and *adaptive machine tool control* which are conventional feedback systems, with controllers having constant parameters. In this entry we take the pragmatic attitude that an adaptive controller is a controller that can modify its *behavior* in response to changes in the dynamics of the process and the character of the disturbances, by adjusting the controller parameters.

Adaptive control has had a colorful history with many ups and downs and intense debates in the research community. It emerged in the 1950s stimulated by attempts to design autopilots for supersonic aircrafts. Autopilots based on constant-gain, linear feedback worked well in one operating condition but not over the whole flight envelope. In process control there was also a need for automatic tuning of simple controllers.

Much research in the 1950s and early 1960s contributed to conceptual understanding of adaptive control. Bellman showed that *dynamic programming* could capture many aspects of adaptation (Bellman 1961). Feldbaum introduced the notion of *dual control*, meaning that control should be probing as well as directing; the controller should thus inject test signals to obtain better information. Tsypkin showed that schemes for *learning and adaptation* could be captured in a common framework (Tsypkin 1971).

Gabor's work on adaptive filtering (Gabor et al. 1959) inspired Widrow to develop an analogue neural network (Adaline) for adaptive control (Widrow 1962). Widrow's adaptation mechanism was inspired by Hebbian learning in biological systems (Hebb 1949).

There are adaptive control problems in economics and operations research. In these fields the problems are often called *decision making*

under uncertainty. A simple idea, called the *certainty equivalence principle* proposed by Simon (1956), is to neglect uncertainty and treat estimates as if they are true. Certainty equivalence was commonly used in early work on adaptive control.

A period of intense research and ample funding ended dramatically in 1967 with a crash of the rocket powered X15-3 using Honeywell's MH-96 self-oscillating adaptive controller. The self-oscillating adaptive control system has, however, been successfully used in several missiles.

Research in adaptive control resurged in the 1970s, when the two schemes the model reference adaptive control (MRAC) and the self-tuning regulator (STR) emerged together with successful applications. The research was influenced by stability theory and advances in the field of system identification. There was an intensive period of research from the late 1970s through the 1990s. The insight and understanding of stability, convergence, and robustness increased. Recently there has been renewed interest because of flight control (Hovakimyan and Cao 2010; Lavretsky and Wise 2013) and other applications; there is, for example a need for adaptation in autonomous systems.

The Brave Era

Supersonic flight posed new challenges for flight control. Eager to obtain results, there was a very short path from idea to flight test with very little theoretical analysis in between. A number of research projects were sponsored by the US air force. Adaptive flight control systems were developed by General Electric, Honeywell, MIT, and other groups. The systems are documented in the Self-Adaptive Flight Control Systems Symposium held at the Wright Air Development Center in 1959 (Gregory 1959) and the book (Mishkin and Braun 1961).

Whitaker of the MIT team proposed the model reference adaptive controller system which is based on the idea of specifying the performance of a servo system by a reference. Honeywell proposed a self-oscillating adaptive system (SOAS)

which attempted to keep a given gain margin by bringing the system to self-oscillation. The system was flight-tested on several aircrafts. It experienced a disaster in a test on the X-15. Combined with the success of gain scheduling based on air data sensors, the interest in adaptive flight control diminished significantly.

There was also interest of adaptation for process control. Foxboro patented an adaptive process controller with a pneumatic adaptation mechanism in 1950 (Foxboro 1950). DuPont had joint studies with IBM aimed at computerized process control. Kalman worked for a short time at the Engineering Research Laboratory at DuPont, where he started work that led to a paper (Kalman 1958), which is the inspiration of the self-tuning regulator. The abstract of this entry has the statement, *This paper examines the problem of building a machine which adjusts itself automatically to control an arbitrary dynamic process*, which clearly captures the dream of early adaptive control.

Draper and Li investigated the problem of operating aircraft engines optimally, and they developed a self-optimizing controller that would drive the system towards optimal working conditions. The system was successfully flight-tested (Draper and Li 1966) and initiated the field of *extremal control*.

Many of the ideas that emerged in the brave era inspired future research in adaptive control. The MRAC, the STR, and extremal control are typical examples.

Model Reference Adaptive Control (MRAC)

The MRAC was one idea from the early work on flight control that had a significant impact on adaptive control. A block diagram of a system with model reference adaptive control is shown in Fig. 1. The system has an ordinary feedback loop with a controller, having adjustable parameters, and the process. There is also a reference model which gives the ideal response y_m to the command signal y_m and a mechanism for adjusting the controller parameters θ . The parameter

History of Adaptive Control, Fig. 1 Block diagram of a feedback system with a model reference adaptive controller (MRAC)

adjustment is based on the process output y , the control signal u , and the output y_m of the reference model. Whitaker proposed the following rule for adjusting the parameters:

$$\frac{d\theta}{dt} = -\gamma e \frac{\partial e}{\partial \theta}, \quad (1)$$

where $e = y - y_m$ and $\partial e / \partial \theta$ is the sensitivity derivative. Efficient ways to compute the sensitivity derivative were already available in sensitivity theory. The adaptation law (1) became known as the *MIT rule*.

Experiments and simulations of the model reference adaptive systems indicated that there could be problems with instability, in particular if the adaptation gain γ in Eq. (1) is large. This observation inspired much theoretical research. The goal was to replace the MIT rule by other parameter adjustment rules with guaranteed stability; the models used were non linear continuous time differential equations. The papers Butchart and Shackcloth (1965) and Parks (1966) demonstrated that control laws could be obtained using Lyapunov theory. When all state variables are measured, the adaptation laws obtained were similar to the MIT rule (1), but the sensitivity function was replaced by linear combinations of states and control variables. The problem was more difficult for systems that only permitted output feedback. Lyapunov theory could still be used if the process transfer function was strictly positive real, establishing a connection with Popov's hyper-stability theory (Landau 1979). The assumption of a positive real process is a severe restriction because such

systems can be successfully controlled by high-gain feedback. The difficulty was finally resolved by using a scheme called *error augmentation* (Monopoli 1974; Morse 1980).

There was much research, and by the late 1980s, there was a relatively complete theory for MRAC and a large body of literature (Egardt 1979; Goodwin and Sin 1984; Anderson et al. 1986; Kumar and Varaiya 1986; Åström and Wittenmark 1989; Narendra and Annaswamy 1989; Sastry and Bodson 1989). The problem of flight control was, however, solved by using gain scheduling based on air data sensors and not by adaptive control (Stein 1980). The MRAC was also extended to nonlinear systems using *backstepping* (Krstić et al. 1993); Lyapunov stability and passivity were essential ingredients in developing the algorithm and analyzing its stability.

The Self-Tuning Regulator

The self-tuning regulator was inspired by steady-state regulation in process control. The mathematical setting was discrete time stochastic systems. A block diagram of a system with a self-tuning regulator is shown in Fig. 2. The system has an ordinary feedback loop with a controller and the process. There is an external loop for adjusting the controller parameters based on real-time parameter estimation and control design. There are many ways to estimate the process parameters and many ways to do the control design. Simple schemes do not take parameter uncertainty into account when computing the

History of Adaptive Control, Fig. 2 Block diagram of a feedback system with a self-tuning regulator (STR)

controller parameters invoking the *certainty equivalence principle*.

Single-input, single-output stochastic systems can be modeled by

$$\begin{aligned} y(t) + a_1 y(t-h) + \dots + a_n y(t-nh) = \\ b_1 u(t-h) + \dots + b_n u(t-nh) + \\ c_1 w(t-h) + \dots + c_n w(t-nh) + e(t), \end{aligned} \quad (2)$$

where u is the control signal, y the process output, w a measured disturbance, and e a stochastic disturbance. Furthermore, h is the sampling period and a_k , b_k and c_k , are the parameters. Parameter estimation is typically done using least squares, and a control design that minimized the variance of the variations was well suited for regulation. A surprising result was that if the estimates converge, the limiting controller is a minimum variance controller even if the disturbance e is colored noise (Åström and Wittenmark 1973). Convergence conditions for the self-tuning regulator were given in Goodwin et al. (1980), and a very detailed analysis was presented in Guo and Chen (1991).

The problem of output feedback does not appear for the model (2) because the sequence of past inputs and outputs $y(t-h), \dots, y(t-nh), u(t-h), \dots, u(t-nh)$ is indeed a state, albeit not a minimal state representation. The continuous analogue would be to use derivatives of states and inputs which is not feasible because of measurement noise. The selection of the sampling period is however important.

Early industrial experience indicated that the ability of the STR to adapt feedforward gains was particularly useful, because feedforward control requires good models.

Insight from system identification showed that *excitation* is required to obtain good estimates. In the absence of excitation, a phenomenon of *bursting* could be observed. There could be epochs with small control actions due to insufficient excitation. The estimated parameters then drifted towards values close to or beyond the stability boundary generating large control actions. Good parameter estimates were then obtained and the system quickly recovered stability. The behavior then repeated in an irregular fashion. There are two ways to deal with the problem. One possibility is to detect when there is poor excitation and stop adaptation (Hägglund and Åström 2000). The other is to inject perturbations when there is poor excitation in the spirit of dual control.

Robustness and Unification

The model reference adaptive control and the self-tuning regulator originate from different application domains, flight control and process control. The differences are amplified because they are typically presented in different frameworks, continuous time for MRAC and discrete time for the STR. The schemes are, however, not too different. For a given process model and given design criterion the process model can often be re-parameterized in terms of controller

parameters, and the STR is then equivalent to an MRAC. Similarly there are indirect MRAC where the process parameters are estimated (Egardt 1979).

A fundamental assumption made in the early analyses of model reference adaptive controllers was that the process model used for analysis had the same structure as the real process. Rohrs at MIT, which showed that systems with guaranteed convergence could be very sensitive to unmodeled dynamics, generated a good deal of research to explore robustness to unmodeled dynamics. Averaging theory, which is based on the observation that there are two loops in an adaptive system, a fast ordinary feedback and a slow parameter adjustment loop, turned out to be a key tool for understanding the behavior of adaptive systems. A large body of theory was generated and many books were written (Sastry and Bodson 1989; Ioannou and Sun 1995).

The theory resulted in several improvements of the adaptive algorithms. In the MIT rule (1) and similar adaptation laws derived from Lyapunov theory, the rate of change of the adaptation rate is a multiplication of the error e with other signals in the system. The adaptation rate may then become very large when signals are large. The analysis of robustness showed that there were advantages in avoiding large adaptation rates by *normalizing* the signals. The stability analysis also required that parameter estimates had to be bounded. To achieve this, parameters were *projected* on regions given by prior parameter bounds. The projection did, however, require prior process knowledge. The improved insight obtained from the robustness analysis is well described in the books Goodwin and Sin (1984), Egardt (1979), Åström and Wittenmark (1989), Narendra and Annaswamy (1989), Sastry and Bodson (1989), Anderson et al. (1986), and Ioannou and Sun (1995).

Applications

There were severe practical difficulties in implementing the early adaptive controllers using the analogue technology available in the

brave era. Kalman used a hybrid computer when he attempted to implement his controller. There were dramatic improvements when mini- and microcomputers appeared in the 1970s. Since computers were still slow at the time, it was natural that most experiments were executed in process control or ship steering which are slow processes. Advances in computing eliminated the technological barriers rapidly.

Self-oscillating adaptive controllers are used in several missiles. In piloted aircrafts there were complaints about the perturbation signals that were always exciting the system.

Self-tuning regulators have been used industrially since the early 1970s. Adaptive autopilots for ship steering were developed at the same time. They outperformed conventional autopilots based on PID control, because disturbances generated by waves were estimated and compensated for. These autopilots are still on the market (Northrop Grumman 2005). Asea (now ABB) developed a small distributed control system, Novatune, which had blocks for self-tuning regulators based on least-squares estimation, and minimum variance control. The company First Control, formed by members of the Novatune team, has delivered SCADA systems with adaptive control since 1985. The controllers are used for high-performance process control systems for pulp mills, paper machines, rolling mills, and pilot plants for chemical process control. The adaptive controllers are based on recursive estimation of a transfer function model and a control law based on pole placement. The controller also admits feedforward. The algorithm is provided with extensive safety logic, parameters are projected, and adaptation is interrupted when variations in measured signals and control signals are too small.

The most common industrial uses of adaptive techniques are automatic tuning of PID controllers. The techniques are used both in single loop controllers and in DCS systems. Many different techniques are used, pattern recognition as well as parameter estimation. The relay auto-tuning has proven very useful and has been shown to be very robust because it provides proper excitation of the process automatically. Some of

the systems use automatic tuning to automatically generate gain schedules, and they also have adaptation of feedback and feedforward gains (Åström and Hägglund 2005).

Summary and Future Directions

Adaptive control has had turbulent history with alternating periods of optimism and pessimism. This history is reflected in the conferences. When the IEEE Conference on Decision and Control started in 1962, it included a Symposium on Adaptive Processes, which was discontinued after the 20th CDC in 1981. There were two IFAC symposia on the Theory of Self-Adaptive Control Systems, the first in Rome in 1962 and the second in Teddington in 1965 (Hammond 1966). The symposia were discontinued but reappeared when the Theory Committee of IFAC created a working group on adaptive control chaired by Prof. Landau in 1981. The group brought the communities of control and signal processing together, and a workshop on Adaptation and Learning in Signal Processing and Control (ALCOSP) was created. The first symposium was held in San Francisco in 1983 and the 11th in Caen in 2013.

Adaptive control can give significant benefits, it can deliver good performance over wide operating ranges, and commissioning of controllers can be simplified. Automatic tuning of PID controllers is now widely used in the process industry. Auto-tuning of more general controller is clearly of interest. Regulation performance is often characterized by the Harris index which compares actual performance with minimum variance control. Evaluation can be dispensed with by applying a self-tuning regulator.

There are adaptive controllers that have been in operation for more than 30 years, for example, in ship steering and rolling mills. There is a variety of products that use scheduling, MRAC, and STR in different ways. Automatic tuning is widely used; virtually all new single loop controllers have some form of automatic tuning. Automatic tuning is also used to build gain schedules semiautomatically. The techniques appear

in tuning devices, in single loop controllers, in distributed systems for process control, and in controllers for special applications. There are strong similarities between adaptive filtering and adaptive control. Noise cancellation and adaptive equalization are widely spread uses of adaptation. The signal processing applications are a little easier to analyze because the systems do not have a feedback controller. New adaptive schemes are appearing. The $\mathcal{L}_1$ adaptive controller is one example. It inherits features of both the STR and the MRAC. The *model-free controller* by Fliess and Join (2013) is another example. It is similar to a continuous time version of the self-tuning regulator.

There is renewed interest in adaptive control in the aerospace industry, both for aircrafts and missiles (Lavretsky and Wise 2013). Good results in flight tests have been reported both using MRAC and the recently developed $\mathcal{L}_1$ adaptive controller (Hovakimyan and Cao 2010).

Adaptive control is a rich field, and to understand it well, it is necessary to know a wide range of techniques: nonlinear, stochastic, and sampled data systems, stability, robust control, and system identification.

In the early development of adaptive control, there was a dream of the universal adaptive controller that could be applied to any process with very little prior process knowledge. The insight gained by the robustness analysis shows that knowledge of bounds on the parameters is essential to ensure robustness. With the knowledge available today, adaptive controllers can be designed for particular applications. Design of proper safety nets is an important practical issue. One useful approach is to start with a basic constant-gain controller and provide adaptation as an add-on. This approach also simplifies design of supervision and safety networks.

There are still many unsolved research problems. Methods to determine the achievable adaptation rates are not known. Finding ways to provide proper excitation is another problem. The dual control formulation is very attractive because it automatically generates proper excitation when it is needed. The computations required to solve the Bellman equations are

prohibitive, except in very simple cases. The self-oscillating adaptive system, which has been successfully applied to missiles, does provide excitation. The success of the relay auto-tuner for simple controllers indicates that it may be called in to provide excitation of adaptive controllers. Adaptive control can be an important component of the emerging autonomous system. One may expect that the current upswing in systems biology may provide more inspiration because many biological clearly have adaptive capabilities.

Human Decision-Making in Multi-agent Systems

Ming Cao

Faculty of Science and Engineering, University of Groningen, Groningen, The Netherlands

Abstract

In order to avoid suboptimal collective behaviors and resolve social dilemmas, researchers have tried to understand how humans make decisions when interacting with other humans or smart machines and carried out theoretical and experimental studies aimed at influencing decision-making dynamics in large populations. We identify the key challenges and open issues in the related research, list a few popular models with the corresponding results, and point out future research directions.

Keywords

Decision making · Multi-agent systems

Introduction

More and more large-scale social, economic, biological, and technological complex systems have been analyzed using models of complex networks of interacting autonomous agents. Researchers are not only interested in using agent-based models to gain insight into how large dynamical networks evolve over time but also keen to introduce control actions into such networks to influence (and/or simulate) the collective behaviors of large populations. This includes

social and economic networks, distributed smart energy grids, intelligent transportation systems, as well as mobile robot and smart sensor networks. However, in practice, such large numbers of interacting autonomous agents making decisions, in particular when humans are involved as participating agents, can result in highly complex, sometimes surprising, and often suboptimal, collective behaviors. It is for this very reason that human decision-making in large multi-agent networks has become a central topic for several research disciplines including economics, sociology, biology, psychology, philosophy, neuroscience, computer science, artificial intelligence, mathematics, robotics, electrical engineering, civil engineering, and last but not least systems and control.

One example to illustrate the complexity is the famous Braess paradox, observed more and more often recently in transportation, communication, and other types of flow networks, in which adding new links can actually worsen the performances of a network and vice versa (Steinberg and Zangwill 1983; Gisches and Rapoport 2012), when each agent decides to optimize its route based on its own local information. Another well-known example is the tragedy of the commons (Ostrom 2008), in which individuals use an excess of a certain shared-resource to maximize their own short-term benefit, leading to the depletion of the resource at a great long-term cost to the group. These considerations impact on a range of emerging engineering applications, e.g., smart transportation and autonomous robots, as well as many of the most pressing current societal concerns, including strategies for energy conservation, improving recycling programs, and reducing carbon emissions.

In order to resolve these types of behavioral and social dilemmas, researchers have tried to gain insight into how humans make decisions when interacting with other autonomous agents, smart machines, or humans and carried out theoretical and experimental studies aimed at influencing decision-making dynamics in large populations in the long run. In fact, control theorists and engineers have been working at the forefront, and a collection of related works

have appeared in the literature. For example, *Proceedings of the IEEE* published in 2012 a special issue on the topic of the decision-making interactions between humans and smart machines (Baillieul et al. 2012). After that, a range of new results have been reported in the literature. In what follows we first identify a few key challenges and difficulties of a number of open issues in the related research, then list a few of the most popular models and the corresponding results, and in the end point out some future research directions.

Challenges and Difficulties

Significantly, when smart machines gain increasing autonomy, empowered by recent breakthroughs in data-driven cognitive learning technologies, they interact with humans in the joint decision-making processes. Humans and smart machines, collectively as networks of autonomous agents, give rise to evolutionary dynamics (Sandholm 2010) that cannot be easily modeled, analyzed, and/or controlled using current systems and control theory that has been effective thus far for engineering practices over the past decades. To highlight the evolutionary nature of the collective decision dynamics, four features can be distinguished:

- (i) Learning and adaption: Autonomous agents may learn and adapt in response to the collaboration or competition pressure from their local peers or an external changing environment.
- (ii) Noise and stochastic effects: Random noise and stochastic deviation are unavoidable in both agents' decisions and the interactions among them.
- (iii) Heterogeneity: Agents differ in their perception capabilities; the agents' interaction patterns co-evolve with the agents' dynamics both in space and time.
- (iv) Availability for control: Some agents may not be available to be controlled directly, and even for those who are, the control is usually in the form of incentives that may only take effect

in the long run or “nudge” the agent in the desired direction.

Therefore, there are still many open problems from the viewpoint of systems and control in developing a general framework for studying human decision-making in multi-agent systems; more generally, there has been an urgent need to develop new theoretical foundations together with computational and experimental tools to tackle the emerging challenging control problems associated with these evolutionary dynamics for networked autonomous agents.

Standard Models and Related Results

Models for human decision-making processes are numerous, and we list a few that are popular and becoming standard especially in the context of multi-agent systems.

Diffusion Model

The standard diffusion model was first proposed by cognitive neural scientists in the 1970s for simple sequential two-choice decision tasks and has been developed into the broader framework known as “evidence accumulation models” (Ratcliff 1978; Ratcliff et al. 2016). The internal process for a human to make a decision is taken to be a process of accumulating evidence from some external stimulus, and once the accumulated evidence is strong enough, a decision is made. More specifically, a one-dimensional drift-diffusion process can be described by the following stochastic differential equation:

$$dz = \alpha dt + \sigma dW, \quad z(0) = 0, \quad (1)$$

where z is the accumulated evidence in favor of a choice of interest, α is the drift rate representing the signal intensity of the stimulus acting on z , and σdW is a Wiener process with the standard deviation σ , called the diffusion rate, representing the effect of white noise. Roughly speaking, when $z(t)$ grows to reach a certain boundary level $\bar{z} > 0$ at time $\bar{t} > 0$, a decision is made at time $\bar{t}$ in favor of the choice that z corresponds

to; otherwise, when another accumulator of some other choice reaches its boundary level first, then a decision favoring that choice is made. Such descriptions match the experimental data recording neural activities when human subjects make sequential decisions in lab environments (Ratcliff et al. 2016). Neural scientists have also used this model to look into the decision time and thus study the speed-accuracy trade-off in decision-making. So far, the model has been successfully applied to a range of cognitive decision-making tasks and used in clinical research (Ratcliff et al. 2016). Researchers from systems and control have looked into the convergence properties of this model (Cao et al. 2010; Woodruff et al. 2012) and used it to predict group decision-making dynamics (Stewart et al. 2012). New applications to robotic systems have also been reported (Reverdy et al. 2015).

Bayesian Model

The Bayesian model, or more generally Bayesian decision theory, is built upon the concepts of Bayesian statistics (Bernardo 1994); when making decisions, humans constantly update their estimates of the beliefs or preference values of different options using new observed inputs through Bayesian inference. It is particularly suitable for multi-alternative, multi-attribute decision-making where observations on different alternatives are dependent (Broder and Schiffer 2004; Evans et al. 2019). Let $p(A_i|x(0), x(1), \dots, x(t))$ denote the posterior belief that alternative A_i is preferred given observations $x(j)$, $0 \leq j \leq t$ up to time $t \geq 0$. Then a Bayesian decision refers to the action at time t of choosing that alternative A_i among all i that maximizes the posterior probability p just given. Note that in some cases, the Bayesian model and diffusion model are closely related (Bitzer et al. 2014). The Bayesian model has found broad applications in dealing with neural and behavior data (Broder and Schiffer 2004; Evans et al. 2019).

Threshold Model

The threshold model is a classic model in sociology to study collective behavior (Granovetter

1978). It stipulates that an individual in a large population will engage in one of several possible behaviors only after a sufficiently large proportion of her surrounding individuals or the population at large have done so. Let the binary state $z_i(t)$ denote the decision of agent i in a large population at time t , $t = 0, 1, 2, \dots$, and $\mathcal{N}_i(t)$ the set of other individuals whose decisions can be observed by agent i at time t . Then the linear threshold model dictates that

$$z_i(t+1) = \begin{cases} 1 & \text{if } \sum_{j \in \mathcal{N}_i(t)} z_j(t) \geq \Theta_i |\mathcal{N}_i(t)| \\ 0 & \text{otherwise,} \end{cases} \quad (2)$$

where $0 < \Theta_i < 1$ is called the *threshold* of agent i and $|\cdot|$ returns the size of the corresponding set. The model or its variants have been widely used to study propagation of beliefs and cascading of social norm violations in social networks (Centola et al. 2016; Mas and Opp 2016). Control theorists have looked into the convergence of dynamics of large populations of individuals whose behaviors follow the threshold model (Ramazi et al. 2016; Rossi et al. 2019).

Evolutionary Game Models

Game theory has been linked to decision-making processes from the day of its birth, and there are several classic textbooks covering the topic, e.g., Myerson (1991). As a branch of game theory, evolutionary game theory is relevant to decision-making in large multi-agent networks especially considering the evolution of proportions of populations making certain decisions over time (Sandholm 2010). It is worth mentioning that under certain conditions, the threshold model turns out to be equivalent to some evolutionary game models (Ramazi et al. 2016). Learning strategies, such as imitation and best response, can be naturally built into different evolutionary game models; the same also holds for network structures and stochastic effects. The notions of *evolutionarily stable strategies* and *stochastically stable strategies* play prominent roles in a variety of studies (Sandholm 2010). There have been reviews on the analysis and

control of evolutionary game dynamics, and we refer the interested reader to Riehl et al. (2018).

Summary and Future Directions

Human decision-making in multi-agent systems remains a fascinating and challenging topic even after various models have been proposed, tested, and compared both theoretically and experimentally in the past few decades. There are several research directions that keep gaining momentum across different disciplines:

- (i) Using dynamical system models to help match human decision-making behavioral data with neural activities in the brain and provides a physiological foundation for decision theories: Although we have listed the diffusion model and Bayesian model and mentioned a few related works, the gap between behavioral and neural findings is still significant, and there is still no widely accepted unified framework that can accommodate both.
- (ii) Better embedding of human decision theory into the fast developing field of network science so that the network effects in terms of information flow and adaptive learning can be better utilized to understand how a human makes decisions within a group of autonomous agents: Threshold models and evolutionary game models are developments in this direction.
- (iii) Influencing and even controlling the decision-making processes: This is still a new area that requires many more novel ideas and accompanying theoretical and empirical analysis. Behavioral and social dilemmas are common in practice, and difficult to prevent for the betterment of society. Systems and control theory can play a major rule in looking for innovative decision policies and intervention rules (Riehl et al. 2018) to steer a network of autonomous agents away from suboptimal collective behaviors and toward behaviors desirable for society.

Human-Building Interaction (HBI)

Burcin Becerik-Gerber
Sonny Astani Department of Civil and
Environmental Engineering, Viterbi School of
Engineering, University of Southern California,
Los Angeles, CA, USA

Abstract

This entry defines and provides an overview of an emerging field, namely, human-building interaction, and identifies some of the key multidisciplinary research directions for this new field. It also provides examples of human-building interaction applications for providing personalized thermal comfort-driven systems, applications for allowing for adaptive light switch and blind control, and a framework for enabling social interactions between buildings and their occupants.

Keywords

Building automation · Intelligent built environments · Energy and comfort management · Trust in automation · Human in the loop control

Definition of Human-Building Interaction

Human-building interaction (HBI), an *emerging field*, represents the dynamic interplay of embodied human and building intelligence; it studies how humans interact, perceive, and navigate through the physical, spatial, and social aspects of the built environment and the artifacts (objects) within it. The field of HBI not only includes buildings but also other built environments people occupy and use, such as public spaces, trains, etc. A new field at the intersection of building science, human computer interaction (HCI), social science, and computer science, HBI entails reciprocal actions/influences of humans and buildings on each other and as a result the change of both building and user behavior. For example, user interactions with building elements, such as windows, fans, heaters, or blinds, would impact both the comfort of users (e.g., changes in lighting levels) and the building performance (e.g., increased solar gain causing cooling system to activate) (Langevin et al. 2016).

Built environments are a collection of artifacts (e.g., spaces, sensors, appliances, lighting, computers, windows, etc.); however, they also entail spatiotemporal experiences. Therefore, one important differentiator of HBI from HCI is the fact that the users are immersed in the physical environment they are interacting with, causing these interactions to have immediate user comfort, user satisfaction, and user acceptability implications. These interactions are also influenced by human behavior (D'Oca et al. 2018; Langevin et al. 2015) (user habits, preferences, requirements) as well as building behavior (usability, aesthetical or architectural quality, indoor environmental quality, and performance, such as safety, sustainability, and maintainability).

HBI Research Directions

Emergence of this new research area requires the collaboration of professionals from multiple disciplines, such as computer scientists, interaction designers, architects, civil engineers, mechanical engineers, and social scientists, to name a few. A summary of essential research directions for the future of the HBI field is provided here.

Intelligent Augmentation. With the unparalleled surge of technological advancements, our spaces (e.g., workplace) will change dramatically in the near future. Considering the variety in building spaces (e.g., offices, schools, post offices, warehouses, homes) and the amount of time we spend in these environments, a natural question is how will our spaces change as a result of intelligent environments? As part of HBI, our built environments should take into account both human-centered and building-centered needs and be “aware” of fatigue, stress levels, psychological states, emotions, and moods of users. Through different modes of HBIs, users can offload some of the tasks to the building, reducing cognitive workload of users and also empowering human users and augmenting their performance where and when needed.

Shared Autonomy. Symbiotic relationships between users and buildings will give birth to new forms of artificial intelligence (AI), which will give buildings an unprecedented autonomy and agency. This will require new kinds of caring relationships and trust between buildings and their users. There are several research questions, for example, how does trust change based on the type of tasks users perform in buildings; how does level of intelligence effect trust between buildings and their users; how should AI be designed for buildings that is easily understandable by building users who might not have any background in AI or similar fields? Moreover, when buildings become intelligent agents that can work for and with human users, the desired level of autonomy (e.g., who does what task and when) should be properly defined and also learned on a continuous basis (Ahmadi-Karvigh et al. 2017).

Mutual Adaptation. Buildings should be capable of continuously sensing the changes in the

environment, different states and time, enabling context-aware sensing of human intent. Based on this acquired knowledge, both the building and the user could adapt to achieve shared goals, for example, energy efficiency by allowing the building to change set points (Ghahramani et al. 2014).

Security and Privacy. With the amount of data collected and stored both about the building and the user and the possibilities to actuate, buildings become hackable. What policies should govern the development and oversight of intelligent environments? What ethical and security measures must be anticipated and addressed? Who should govern the new codes and standards?

New Interfaces. Users and buildings create considerable amounts of data; how to mine and use this information for remembering and reusing of events and activities within a space becomes an interesting question. Moreover, there will exist a need for buildings and users to communicate. How to better design buildings to provide novel interaction opportunities to bi-directionally communicate with their users? What interaction types influence human perception of space and how? How does the style of interaction impact how we perceive our environments? How to enable a building’s lifelong interaction with humans? How to adapt interfaces/modalities based on tasks and users?

Education. We need to rethink our curriculum to be able to educate future engineers who can address the complexities of HBIs and broaden our engineering objectives to include human objectives, incorporating the complexity and dynamism of built environments rather than treating them as unmanageable. In addition, we need to incorporate more computational thinking in our traditional engineering curricula. At the same time, we need to educate building users and building managers to ensure sustainable technology adoption.

HBI Applications and Examples

HBI Framework for Personalized Thermal Comfort-Driven Systems. Jazizadeh et al. (2014a) developed an HBI framework for

Human-Building Interaction (HBI), Fig. 1 Human-building interaction framework proposed in Jazizadeh et al. (2014a)

integrating building user's thermal comfort preferences into the HVAC control loop. To do so, they have developed an HBI interface, using participatory sensing via smartphones, and collected occupants' comfort perception indices (i.e., comfort votes provided by users and mapped to a numerical value) and ambient temperature data through a sensor network. They computed comfort profiles for each user using a fuzzy rule-based descriptive and predictive model. Implementation of the personalized comfort profiles in the HVAC system was tested through actuation via a proportional controller algorithm in a building. The study proved that the algorithm was capable of keeping the zone temperatures within the range of user's thermal comfort preferences. In a follow-up study (Jazizadeh et al. 2014b), the researchers further tested the framework and demonstrated comfort improvements along with a 39% reduction in daily average airflow when the occupant comfort preferences were used (Fig. 1).

HBI Framework for Adaptive Light Switch and Blind Control. Gunay et al. (2017) analyzed the light switch and blind use behavior of occupants in private offices and developed an

adaptive control algorithm for lighting and blinds. Using the observed behavioral data (use of light switches and blinds), the algorithm learns the occupants' illuminance preferences, uses this information to determine photosensor setpoints, and switches off lighting and opens the blinds. The researchers tested the controller in private offices and shared office spaces and found that the solution could substantially reduce the lighting loads (around 25%) in office buildings without compromising the occupant's visual comfort. In another study, also focusing on personalized daylighting control for optimizing visual satisfaction and lighting energy use (Xiong et al. 2019), the researchers developed a personalized shading control framework. This optimization framework used personalized visual satisfaction utility functions and model-predicted lighting energy. Instead of assigning arbitrary weights to objectives, the researchers allowed users to make the final decisions in real time using a slider that balanced personal visual satisfaction and lighting energy use.

HBI Framework for Enabling Social Interactions Between Buildings and Their Users. Khashe et al. (2017) investigated the influence of direct

Human-Building Interaction (HBI), Fig. 2 Female and male avatar representing the building or building manager and communicate with the building occupants (Khashe et al. 2017)

communication between buildings and their users and tested the effectiveness of communicator styles (i.e., avatar, voice, and text) and communicator gender (i.e., female and male) and personification (communicator being either a building or building manager) on building occupant's compliance with pro-environmental requests. While the users were completing an office task (reading a passage), a request was presented to the user delivered through a combination of style, gender, and persona. An example of the request was *"If I open the blinds for you to have natural light, would you please dim or turn off the artificial lights?"* They found that the avatar was more effective than the voice and the voice was more effective than the text requests. Users complied more when the communicator was a female agent and when they thought the communicator was the building manager. In a follow-up study (Khashe et al. 2018), the researchers tested the effectiveness of social dialogue instead of a single request. They again tested two personas, building manager and building, however, this time only with female avatar communicator. The avatar started with a small talk, introduced herself (either as the building or building manager), told the user her name and asked the user's name, and so on, and then followed up with the request. They found that social dialogue persuaded the users to perform more pro-environmental actions. However, differently than the findings in their previous study, when the agent got engaged in a social

dialogue with the users, they complied more with the requests if they thought the building was communicating with them. This two-tier study is one of the examples of personification of buildings through digital artifacts with the aim of building a relationship between an inanimate object (i.e., a building) and its users for achieving a shared goal (i.e., pro-environmentalism) (Fig. 2).

Engineering, University of California, Santa
Cruz, CA, USA

Abstract

The control of systems with hybrid dynamics requires algorithms capable of dealing with

the intricate combination of continuous and discrete behavior, which typically emerges from the presence of continuous processes, switching devices, and logic for control. Several analysis and design techniques have been proposed for the control of nonlinear continuous-time plants, but little is known about controlling plants that feature truly hybrid behavior. This short entry focuses on recent advances in the design of feedback control algorithms for hybrid dynamical systems. The focus is on hybrid feedback controllers that are systematically designed employing Lyapunov-based methods. The control design techniques summarized in this entry include control Lyapunov function-based control, passivity-based control, trajectory tracking control, safety, and temporal logic.

Keywords

Feedback control · Hybrid control · Hybrid systems · Asymptotic stability

Introduction

A *hybrid control system* is a *feedback system* whose variables may flow and, at times, jump. Such a hybrid behavior can be present in one or more of the subsystems of the feedback system: in the system to control, i.e., *the plant*; in the algorithm used for control, i.e., *the controller*; or in the subsystems needed to interconnect the plant and the controller, i.e., *the interfaces/signal conditioners*. Figure 1 depicts a feedback system in closed-loop configuration with such subsystems under the presence of environmental disturbances. Due to its hybrid dynamics, a hybrid control system is a particular type of *hybrid dynamical system*.

Motivation

Hybrid dynamical systems are ubiquitous in science and engineering as they permit capturing the complex and intertwined continuous/discrete

Hybrid Dynamical Systems, Feedback Control of,
Fig. 1 A hybrid control system: a feedback system with a plant, controller, and interfaces/signal conditioners

(along with environmental disturbances) as subsystems featuring variables that flow and, at times, jump

behavior of a myriad of systems with variables that flow and jump. The recent popularity of feedback systems combining physical and software components demands tools for stability analysis and control design that can systematically handle such a complex combination. To avoid the issues due to approximating the dynamics of a system, in numerous settings, it is mandatory to keep the system dynamics as pure as possible and to be able to design feedback controllers that can cope with flow and jump behavior in the system.

Modeling Hybrid Control Systems

In this entry, hybrid control systems are represented in the framework of *hybrid equations/inclusions* for the study of hybrid dynamical systems. Within this framework, the continuous dynamics of the system are modeled using a differential equation/inclusion, while the discrete dynamics are captured by a difference equation/inclusion. A solution to such a system can *flow* over nontrivial intervals of time and *jump* at certain time instants. The conditions determining whether a solution to a hybrid system should flow or jump are captured by subsets of the state space and input space of the hybrid control system. In this way, a *plant* with hybrid dynamics can be modeled by the hybrid inclusion (This hybrid inclusion captures the dynamics of (constrained or unconstrained)

continuous-time systems when $D_P = \emptyset$ and G_P is arbitrary. Similarly, it captures the dynamics of (constrained or unconstrained) discrete-time systems when $C_P = \emptyset$ and F_P is arbitrary. Note that while the output inclusion does not explicitly include a constraint on (z, u) , the output map is only evaluated along solutions.)

$$\mathcal{H}_P : \begin{cases} \dot{z} \in F_P(z, u) & (z, u) \in C_P \\ z^+ \in G_P(z, u) & (z, u) \in D_P \\ y = h(z, u) \end{cases} \quad (1)$$

where z is the *state* of the plant and takes values from the Euclidean space $\mathbb{R}^{n_P}$, u is the *input* and takes values from $\mathbb{R}^{m_P}$, y is the *output* and takes values from the output space $\mathbb{R}^{r_P}$, and (C_P, F_P, D_P, G_P, h) is the *data* of the hybrid system. The set C_P is the *flow set*, the set-valued map F_P is the *flow map*, the set D_P is the *jump set*, the set-valued map G_P is the *jump map*, and the single-valued map h is the *output map*. In (1), $\dot{z}$ denotes time derivative and z^+ denotes an instantaneous change in z .

Example 1 (controlled bouncing ball) Consider the juggling system consisting of a ball moving vertically and bouncing on a fixed horizontal surface. The surface, located at the origin of the line of motion, is equipped with a mechanical actuator that controls the speed of the ball resulting after impacts. From a physical viewpoint, control authority may be obtained varying the viscoelastic properties of the surface and, in turn,

the coefficient of restitution of the surface. The position and the velocity of the ball are denoted as z_1 and z_2 , respectively. Between bounces, the free motion of the ball is given by

$$\dot{z}_1 = z_2, \quad \dot{z}_2 = -\gamma \quad (2)$$

where $\gamma > 0$ is the gravity constant. The conditions at which impacts occur are modeled as

$$z_1 = 0 \text{ and } z_2 \leq 0 \quad (3)$$

while the new value of the state variables after each impact is described by the difference equations

$$z_1^+ = z_1, \quad z_2^+ = u \quad (4)$$

where u , which is larger than or equal to zero, is the controlled velocity after impacts, capturing the effect of the mechanism installed on the horizontal surface. In this way, the data (C_P, F_P, D_P, G_P, h) of the bouncing ball model is defined as follows:

$$\begin{aligned} F_P(z, u) &:= \begin{bmatrix} z_2 \\ -\gamma \end{bmatrix} & \forall (z, u) \in C_P &:= \left\{ (z, u) \in \mathbb{R}^2 \times \mathbb{R} : z_1 \geq 0 \right\} \\ G_P(z, u) &:= \begin{bmatrix} z_1 \\ u \end{bmatrix} & \forall (z, u) \in D_P &:= \left\{ (z, u) \in \mathbb{R}^2 \times \mathbb{R} : z_1 = 0, z_2 \leq 0 \right\} \end{aligned}$$

and, when assuming that the state z is measured, the output map is $h(z, u) = z$. $\triangle$

Other examples of hybrid plants whose dynamics can be captured by $\mathcal{H}_P$ in (1) include walking robots, network control systems, and spiking neurons. Systems with different modes of operation can also be modeled as $\mathcal{H}_P$ and, as the following example illustrates, can be captured by the constrained differential equation (or inclusion) part of $\mathcal{H}_P$. Such systems are not necessarily hybrid – at least as the term *hybrid* is used in this short entry – since they can be modeled by a dynamical system with state that only evolves continuously.

Example 2 (Thermostat system) The evolution of the temperature of a room under the effect of a heater can be modeled by a differential equation with constraints on its input. The temperature of the room is denoted by z and takes values from $\mathbb{R}$. The input is given by the pair $u = (u_1, u_2)$, where u_1 denotes whether the heater is turned on ($u_1 = 1$) or turned off ($u_1 = 0$) – these are the constraints on the inputs – while u_2 denotes the temperature outside the room, which can assume any value in $\mathbb{R}$. With these definitions, the evolution of the temperature z is governed by

$$\dot{z} = -z + \begin{bmatrix} z_\Delta & 1 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}$$

$$(z, u) \in C_P = \left\{ (z, u) \in \mathbb{R} \times \mathbb{R}^2 : u_1 \in \{0, 1\} \right\} \quad (5)$$

where z_Δ is a positive constant representing the heater capacity. Note that C_P captures the constraint on the input u_1 , which restricts it to the values 0 and 1. $\triangle$

Given an input u , a *solution to a hybrid inclusion* is defined by a state trajectory ϕ that satisfies the inclusions. Both the input and the state trajectory are functions of $(t, j) \in \mathbb{R}_{\geq 0} \times \mathbb{N} := [0, \infty) \times \{0, 1, 2, \dots\}$, where t keeps track of the amount of flow while j counting the number of jumps of the solution. These functions are given by *hybrid arcs* and *hybrid inputs*, which are defined on *hybrid time domains*. More precisely, hybrid time domains are subsets E of $\mathbb{R}_{\geq 0} \times \mathbb{N}$ that, for each $(T', J') \in E$,

$$E \cap ([0, T'] \times \{0, 1, \dots, J'\})$$

can be written in the form

$$\bigcup_{j=0}^{J-1} ([t_j, t_{j+1}], j)$$

for some finite sequence of times $0 = t_0 \leq t_1 \leq t_2 \leq \dots \leq t_J$, $J \in \mathbb{N}$. A hybrid arc ϕ is a function on a hybrid time domain. (The set $E \cap ([0, T] \times \{0, 1, \dots, J\})$ defines a compact hybrid time domain since it is bounded and closed.) The hybrid time domain of ϕ is denoted by $\text{dom } \phi$. A hybrid arc is such that, for each $j \in \mathbb{N}$, $t \mapsto \phi(t, j)$ is locally absolutely continuous on intervals of flow $I^j := \{t : (t, j) \in \text{dom } \phi\}$ with nonzero Lebesgue measure. A hybrid input u is a function on a hybrid time domain that, for each $j \in \mathbb{N}$, $t \mapsto u(t, j)$ is Lebesgue measurable and locally essentially bounded on the interval I^j .

In this way, a solution to the plant $\mathcal{H}_P$ is given by a pair (ϕ, u) with $\text{dom } \phi = \text{dom } u$ ($= \text{dom}(\phi, u)$) satisfying

(S0) $(\phi(0, 0), u(0, 0)) \in \bar{C}_P$ or $(\phi(0, 0), u(0, 0)) \in D_P$, and $\text{dom } \phi = \text{dom } u$;

(S1) For each $j \in \mathbb{N}$ such that I^j has nonempty interior $\text{int}(I^j)$, we have

$$(\phi(t, j), u(t, j)) \in C_P \quad \text{for all } t \in \text{int}(I^j)$$

and

$$\frac{d}{dt} \phi(t, j) \in F_P(\phi(t, j), u(t, j))$$

for almost all $t \in I^j$

(S2) For each $(t, j) \in \text{dom}(\phi, u)$ such that $(t, j+1) \in \text{dom}(\phi, u)$, we have

$$(\phi(t, j), u(t, j)) \in D_P$$

and

$$\phi(t, j+1) \in G_P(\phi(t, j), u(t, j))$$

A solution pair (ϕ, u) to $\mathcal{H}$ is said to be *complete* if $\text{dom}(\phi, u)$ is unbounded and *maximal* if there does not exist another pair $(\phi, u)'$ such that (ϕ, u) is a truncation of $(\phi, u)'$ to some proper subset of $\text{dom}(\phi, u)'$. A solution pair (ϕ, u) to $\mathcal{H}$ is said to be *Zeno* if it is complete and the projection of $\text{dom}(\phi, u)$ onto $\mathbb{R}_{\geq 0}$ is bounded.

On decomposition of inputs and outputs: At times, it is convenient to define inputs $u_c \in \mathbb{R}^{m_{P,c}}$ and $u_d \in \mathbb{R}^{m_{P,d}}$ collecting every component of the input u that affect flows and that affect jumps, respectively (Some of the components of u can be used to define both u_c and u_d , that is, there could be inputs that affect both flows and jumps.). Similarly, one can define y_c and y_d as the components of y that are measured during flows and jumps, respectively.

To control the hybrid plant $\mathcal{H}_P$ in (1), control algorithms that can cope with the nonlinearities introduced by the flow and jump equations/inclusions are required. In general, feedback controllers designed using classical techniques from the continuous-time and discrete-time domain fall short. Due to this limitation, hybrid feedback controllers would be more suitable for the control of plants with hybrid dynamics. Then, following the hybrid plant model above, hybrid controllers for the plant $\mathcal{H}_P$ in (1) will be given by the hybrid inclusion:

$$\mathcal{H}_K : \begin{cases} \dot{\eta} \in F_K(\eta, v) & (\eta, v) \in C_K \\ \eta^+ \in G_K(\eta, v) & (\eta, v) \in D_K \\ \zeta = \kappa(\eta, v) \end{cases} \quad (6)$$

where η is the *state* of the controller and takes values from the Euclidean space $\mathbb{R}^{n_K}$, v is the *input* and takes values from $\mathbb{R}^{r_P}$, ζ is the *output* and takes values from the output space $\mathbb{R}^{m_P}$, and $(C_K, F_K, D_K, G_K, \kappa)$ is the *data* of the hybrid inclusion defining the hybrid controller.

The control of $\mathcal{H}_P$ via $\mathcal{H}_K$ defines an interconnection through the input/output assignment $u = \zeta$ and $v = y$; the system in Fig. 1 without interfaces represents this interconnection. The resulting closed-loop system is a hybrid dynamical system given in terms of a hybrid inclusion/equation with state $x = (z, \eta)$. We will denote such a closed-loop system by $\mathcal{H}$, with data denoted (C, F, D, G) , state $x \in \mathbb{R}^n$, and dynamics:

$$\mathcal{H} : \begin{cases} \dot{x} \in F(x) & x \in C \\ x^+ \in G(x) & x \in D \end{cases} \quad (7)$$

Its data can be constructed from the data (C_P, F_P, D_P, G_P, h) and $(C_K, F_K, D_K, G_K, \kappa)$ of each of the subsystems. Solutions to both $\mathcal{H}_K$ and $\mathcal{H}$ are understood following the notion introduced above for $\mathcal{H}_P$.

Definitions and Notions

For convenience, we use the equivalent notation $[x^\top \ y^\top]^\top$ and (x, y) for vectors x and y . Also, we denote by $\mathcal{K}_\infty$ the class of functions from $\mathbb{R}_{\geq 0}$ to $\mathbb{R}_{\geq 0}$ that are continuous, zero at zero, strictly increasing, and unbounded.

In general, the dynamics of hybrid inclusions have right-hand sides given by set-valued maps. Unlike functions or single-valued maps, set-valued maps may return a set when evaluated at a point. For instance, at points in C_P , the set-valued flow map F_P of the hybrid plant $\mathcal{H}_P$ might return more than one value, allowing for different values of the derivative of z . A particular continuity property of set-valued maps that will be needed later is lower semicontinuity. A set-valued map S from $\mathbb{R}^n$ to $\mathbb{R}^m$ is lower semicontinuous if for each $x \in \mathbb{R}^n$ one has that $\liminf_{x_i \rightarrow x} S(x_i) \supset S(x)$, where $\liminf_{x_i \rightarrow x} S(x_i) = \{z : \forall x_i \rightarrow x, \exists z_i \rightarrow z \text{ s.t. } z_i \in S(x_i)\}$ is the so-called inner limit of S .

A vast majority of control problems consist of designing a feedback algorithm that assures that a function of the solutions to the plant approach a desired set-point condition (*attractivity*) and, when close to it, the solutions remain nearby (*stability*). In some scenarios, the desired set-point condition is not necessarily an isolated point, but rather a set. The problem of designing a hybrid controller $\mathcal{H}_K$ for a hybrid plant $\mathcal{H}_P$ typically pertains to the stabilization of sets, in particular, due to the hybrid state of the controller including timers that persistently evolve within a bounded time interval and logic variables that take values from discrete sets. Denoting by $\mathcal{A}$ the set of points to stabilize for the closed-loop system $\mathcal{H}$ and $|\cdot|_{\mathcal{A}}$ as the distance to such set, the following property captures the typically desired properties outlined above. A closed set $\mathcal{A}$ is said to be

- (S) *Stable* if for each $\varepsilon > 0$ there exists $\delta > 0$ such that each maximal solution ϕ to $\mathcal{H}$ with $\phi(0, 0) = x_o$, $|x_o|_{\mathcal{A}} \leq \delta$ satisfies $|\phi(t, j)|_{\mathcal{A}} \leq \varepsilon$ for all $(t, j) \in \text{dom } \phi$;
- (pA) *Pre-attractive* if there exists $\mu > 0$ such that every maximal solution ϕ to $\mathcal{H}$ with $\phi(0, 0) = x_o$, $|x_o|_{\mathcal{A}} \leq \mu$ is bounded and if it is complete satisfies $\lim_{(t, j) \in \text{dom } \phi, t+j \rightarrow \infty} |\phi(t, j)|_{\mathcal{A}} = 0$;
- (FTpA) *Finite time pre-attractive* if there exists $\mu > 0$ such that every maximal solution ϕ to $\mathcal{H}$ with $\phi(0, 0) = x_o$, $|x_o|_{\mathcal{A}} \leq \mu$ is such that $|\phi(t, j)|_{\mathcal{A}} = 0$ for some $(t, j) \in \text{dom } \phi$;
- (pAS) *Pre-asymptotically stable* if it is stable and pre-attractive.

The basin of pre-attraction of a pre-asymptotically stable set $\mathcal{A}$ is the set of points from where the pre-attractivity property holds. The set $\mathcal{A}$ is said to be globally pre-asymptotically stable when the basin of pre-attraction is equal to the entire state space. Similarly, notions pertaining to finite-time stability and basin of attraction for finite-time stability can be defined. When every maximal solution is complete, then the prefix “pre” can be dropped since, in that case, the notions resemble those for continuous-time or discrete-time systems with solutions defined for all time.

At times, one is interested in asserting convergence when the state trajectory or the output remains in a set. For instance, a dynamical system (with assigned inputs) is said to be detectable when its output being held to zero implies that its state converges to the origin (or to a particular set of interest). A similar property can be defined for hybrid dynamical systems, for a general set K , which may not necessarily be the set of points at which the output is zero. For the closed-loop system $\mathcal{H}$, given sets $\mathcal{A}$ and K , the distance to $\mathcal{A}$ is said to be

- (D) *0-input detectable relative to K* if every complete solution ϕ to $\mathcal{H}$ is such that

$$\phi(t, j) \in K \quad \forall (t, j) \in \text{dom } \phi \quad \Rightarrow \quad \lim_{(t, j) \in \text{dom } \phi, t+j \rightarrow \infty} |\phi(t, j)|_{\mathcal{A}} = 0$$

Note that “ $\phi(t, j) \in K$ ” captures the “output being held to zero”-like property in the usual detectability notion.

In addition to stability, attractivity, and detectability, in this short note, we are interested in hybrid controllers that guarantee that a set K is forward invariant in the following sense:

- (FpI) *Forward pre-invariant* if each maximal solution ϕ to $\mathcal{H}$ with $\phi(0, 0) = x_o, x_o \in K$, satisfies $\phi(t, j) \in K$ for all $(t, j) \in \text{dom } \phi$.
- (FI) *Forward invariant* if each maximal solution ϕ to $\mathcal{H}$ with $\phi(0, 0) = x_o, x_o \in K$, is complete and satisfies $\phi(t, j) \in K$ for all $(t, j) \in \text{dom } \phi$.

Feedback Control Design for Hybrid Dynamical Systems

Several methods for the design of a hybrid controller $\mathcal{H}_K$ rendering a given set $\mathcal{A}$ such that the properties defined in section “Definitions and Notions” are given below. At the core of these methods are sufficient conditions in terms of Lyapunov-like functions guaranteeing properties such as asymptotic stability, invariance, and finite-time attractivity of a set. Some of the methods presented below exploit such sufficient conditions when applied to the closed-loop system $\mathcal{H}$, while others exploit the properties of the hybrid plant to design controllers with a particular structure.

CLF-Based Control Design

In simple terms, a control Lyapunov function (CLF) is a regular enough scalar function that decreases along solutions to the system for some values of the unassigned input. When such a function exists, it is very tempting to exploit its properties to construct an asymptotically stabilizing control law. Following the ideas from the literature of continuous-time and discrete-time nonlinear systems, we define control Lyapunov functions for hybrid plants $\mathcal{H}_P$ and present results on CLF-based

control design. For simplicity, as mentioned in the *input and output modeling remark* in section “Definitions and Notions”, we use inputs u_c and u_d instead of u . Also, for simplicity, we restrict the discussion to sets $\mathcal{A}$ that are compact as well as hybrid plants with F_P, G_P single-valued and such that $h(z, u) = z$. For notational convenience, we use Π to denote the “projection” of C_P and D_P onto $\mathbb{R}^{n_P}$, i.e., $\Pi(C_P) = \{z : \exists u_c \text{ s.t. } (z, u_c) \in C_P\}$ and $\Pi(D_P) = \{z : \exists u_d \text{ s.t. } (z, u_d) \in D_P\}$, and the set-valued maps $\Psi_c(z) = \{u_c : (z, u_c) \in C_P\}$ and $\Psi_d(z) = \{u_d : (z, u_d) \in D_P\}$.

Given a compact set $\mathcal{A}$, a continuously differentiable function $V : \mathbb{R}^{n_P} \rightarrow \mathbb{R}$ is a *control Lyapunov function for $\mathcal{H}_P$ with respect to $\mathcal{A}$* if there exist $\alpha_1, \alpha_2 \in \mathcal{K}_\infty$ and a continuous, positive definite function ρ such that

$$\alpha_1(|z|_{\mathcal{A}}) \leq V(z) \leq \alpha_2(|z|_{\mathcal{A}})$$

$$\forall z \in \mathbb{R}^{n_P}$$

$$\inf_{u_c \in \Psi_c(z)} \langle \nabla V(z), F_P(z, u_c) \rangle \leq -\rho(|z|_{\mathcal{A}})$$

$$\forall z \in \Pi(C_P) \quad (8)$$

$$\inf_{u_d \in \Psi_d(z)} V(G_P(z, u_d)) - V(z) \leq -\rho(|z|_{\mathcal{A}})$$

$$\forall z \in \Pi(D_P) \quad (9)$$

With the availability of a CLF, the set $\mathcal{A}$ can be asymptotically stabilized if it is possible to synthesize a controller $\mathcal{H}_K$ from inequalities (8) and (9). Such a synthesis is feasible, in particular, for the special case of $\mathcal{H}_K$ being a static state-feedback law $z \mapsto \kappa(z)$. Sufficient conditions guaranteeing the existence of such a controller as well as a particular state-feedback law with point-wise minimum norm are given next.

Given a compact set $\mathcal{A}$ and a control Lyapunov function V (with respect to $\mathcal{A}$), define, for each $r \geq 0$, the set $\mathcal{I}(r) := \{z \in \mathbb{R}^{n_P} : V(z) \geq r\}$. Moreover, for each (z, u_c) and $r \geq 0$, define the function

$$\Gamma_c(z, u_c, r) := \begin{cases} \langle \nabla V(z), F_P(z, u_c) \rangle + \frac{1}{2} \rho(|z|_{\mathcal{A}}) & \text{if } (z, u_c) \in C_P \cap (\mathcal{I}(r) \times \mathbb{R}^{m_{P,c}}), \\ -\infty & \text{otherwise} \end{cases}$$

and, for each (z, u_d) and $r \geq 0$, the function

$$\Gamma_d(z, u_d, r) := \begin{cases} V(G_P(z, u_d)) - V(z) + \frac{1}{2} \rho(|z|_{\mathcal{A}}) & \text{if } (z, u_d) \in D_P \cap (\mathcal{I}(r) \times \mathbb{R}^{m_{P,d}}), \\ -\infty & \text{otherwise} \end{cases}$$

It can be shown that the following conditions involving V and the data (C_P, F_P, D_P, G_P, h) of $\mathcal{H}_P$ guarantee that, for each $r > 0$, there exists a state-feedback law

$$z \mapsto \kappa(z) = (\kappa_c(z), \kappa_d(z))$$

with κ_c continuous on $\Pi(C_P) \cap \mathcal{I}(r)$ and κ_d continuous on $\Pi(D_P) \cap \mathcal{I}(r)$ rendering the compact set

$$\mathcal{A}_r := \{z \in \mathbb{R}^{n_P} : V(z) \leq r\}$$

pre-asymptotically stable for $\mathcal{H}_P$:

(CLF1) C_P and D_P are closed sets, and F_P and G_P are continuous;

(CLF2) The set-valued maps $\Psi_c(z) = \{u_c : (z, u_c) \in C_P\}$ and $\Psi_d(z) = \{u_d : (z, u_d) \in D_P\}$ are lower semicontinuous with convex values;

(CLF3) For every $r > 0$, we have that, for every $z \in \Pi(C_P) \cap \mathcal{I}(r)$, the function $u_c \mapsto \Gamma_c(z, u_c, r)$ is convex on $\Psi_c(z)$ and that, for every $z \in \Pi(D_P) \cap \mathcal{I}(r)$, the function $u_d \mapsto \Gamma_d(z, u_d, r)$ is convex on $\Psi_d(z)$;

In addition to guaranteeing the existence of a (continuous) state-feedback law practically pre-asymptotically stabilizing the set $\mathcal{A}$, these conditions also lead to the following natural definition of the feedback: for every $r > 0$, the state-feedback law pair

$$\kappa_c : \Pi(C_P) \rightarrow \mathbb{R}^{m_{P,c}}, \quad \kappa_d : \Pi(D_P) \rightarrow \mathbb{R}^{m_{P,d}}$$

can be defined on $\Pi(C_P)$ and $\Pi(D_P)$ as

$$\kappa_c(z) := \arg \min \{|u_c| : u_c \in \mathcal{T}_c(z)\} \quad \forall z \in \Pi(C_P) \cap \mathcal{I}(r)$$

$$\kappa_d(z) := \arg \min \{|u_d| : u_d \in \mathcal{T}_d(z)\} \quad \forall z \in \Pi(D_P) \cap \mathcal{I}(r)$$

where $\mathcal{T}_c(z) = \Psi_c(z) \cap \{u_c : \Gamma_c(z, u_c, V(z)) \leq 0\}$ and $\mathcal{T}_d(z) = \Psi_d(z) \cap \{u_d : \Gamma_d(z, u_d, V(z)) \leq 0\}$.

The stability property guaranteed by this feedback is also practical. Under further properties, similar results hold when the input u is not partitioned into u_c and u_d . To achieve asymptotic stability (or stabilizability) of $\mathcal{A}$ with a continuous state-feedback law, extra conditions are required to hold nearby the compact set, which for the case of stabilization of continuous-time systems are the so-called small control

properties. Furthermore, the continuity of the feedback law assures that the closed-loop system has closed flow and jump sets as well as continuous flow and jump maps, which, in turn, due to the compactness of $\mathcal{A}$, implies that the asymptotic stability property is robust. Robustness follows from results for hybrid systems without inputs.

Example 3 (controlled bouncing ball revisited) For the juggling system in Example 1, the feed-

back law $u = \kappa_d \equiv 0$ asymptotically stabilizes its origin – note that for this system, $u_d = u$. In fact, with this feedback, after the first impact (or jump), every solution remains at the origin.

Passivity-Based Control Design

Dissipativity and its special case, passivity, provide a useful physical interpretation of a feedback control system as they characterize the exchange of energy between the plant and its controller. For an open system, passivity (in its very pure form) is the property that the energy stored in the system is no larger than the energy it has absorbed over a period of time. The energy stored in a system is given by the difference between the initial and final energy over a period of time, where the energy function is typically called the storage function. Hence, conveniently, passivity can be expressed in terms of the derivative of a storage function (i.e., the rate of change of the internal energy) and the product between inputs and outputs (i.e., the power flow of the system). Under further observability conditions, this power inequality can be employed as a design tool by selecting a control law that makes the rate of change of the internal energy negative. This method is called *passivity-based control design*.

The passivity-based control design method can be employed in the design of a controller for a “passive” hybrid plant $\mathcal{H}_P$, in which energy might be dissipated during flows, jumps, or both. Passivity notions and a passivity-based control design method for hybrid plants are given next. Since the form of the output of the plant plays a key role in asserting a passivity property, and this property may not necessarily hold both during flows and jumps, as mentioned in the *input and output modeling remark* in section “[Definitions and Notions](#)”, we define outputs y_c and y_d , which, for simplicity, are assumed to be single-valued: $y_c = h_c(x)$ and $y_d = h_d(x)$. Moreover, we consider the case when the dimension of the space of the inputs u_c and u_d coincides with that of the outputs y_c and y_d , respectively, i.e., a “duality” of the output and input space.

Given a compact set $\mathcal{A}$ and functions h_c, h_d such that $h_c(\mathcal{A}) = h_d(\mathcal{A}) = 0$, a hybrid plant $\mathcal{H}_P$ for which there exists a continuously differ-

entiable function $V : \mathbb{R}^{n_P} \rightarrow \mathbb{R}_{\geq 0}$ satisfying for some functions $\omega_c : \mathbb{R}^{m_{P,c}} \times \mathbb{R}^{n_P} \rightarrow \mathbb{R}$ and $\omega_d : \mathbb{R}^{m_{P,c}} \times \mathbb{R}^{n_P} \rightarrow \mathbb{R}$

$$\langle \nabla V(z), F_P(z, u_c) \rangle \leq \omega_c(u_c, z) \forall (z, u_c) \in C \quad (10)$$

$$V(G_P(z, u_d)) - V(z) \leq \omega_d(u_d, z) \forall (z, u_d) \in D \quad (11)$$

is said to be *passive with respect to a compact set* $\mathcal{A}$ if

$$(u_c, z) \mapsto \omega_c(u_c, z) = u_c^\top y_c \quad (12)$$

$$(u_d, z) \mapsto \omega_d(u_d, z) = u_d^\top y_d \quad (13)$$

The function V is the so-called storage function. If (10) holds with ω_c as in (12), and (11) holds with $\omega_d \equiv 0$, then the system is called *flow-passive*, i.e., the power inequality holds only during flows. If (10) holds with $\omega_c \equiv 0$, and (11) holds with ω_d as in (13), then the system is called *jump-passive*, i.e., the energy of the system decreases only during jumps.

Under additional detectability properties, these passivity notions can be used to design static output feedback controllers. In fact, given a hybrid plant $\mathcal{H}_P = (C_P, F_P, D_P, G_P, h)$ satisfying

(PBC1) C_P and D_P are closed sets; F_P and G_P are continuous; and h_c and h_d are continuous;

and a compact set $\mathcal{A}$, it can be shown that if $\mathcal{H}_P$ is flow-passive with respect to $\mathcal{A}$ with a storage function V that is positive definite with respect to $\mathcal{A}$ and has compact sublevel sets, and if there exists a continuous function $\kappa_c : \mathbb{R}^{m_{P,c}} \rightarrow \mathbb{R}^{m_{P,c}}$, $y_c^\top \kappa_c(y_c) > 0$ for all $y_c \neq 0$, such that the resulting closed-loop system with $u_c = -\kappa_c(y_c)$ and $u_d \equiv 0$ has the following properties:

(PBC2) The distance to $\mathcal{A}$ is detectable relative to

$$\{z \in \Pi(C_P) \cup \Pi(D_P) \cup G_P(D_P) :$$

$$h_c(z)^\top \kappa_c(h_c(z)) = 0, (z, -\kappa_c(h_c(z))) \in C_P\};$$

(PBC3) Every complete solution ϕ is such that, for some $\delta > 0$ and some $J \in \mathbb{N}$, we have $t_{j+1} - t_j \geq \delta$ for all $j \geq J$;

then the output-feedback law

$$u_c = -\kappa_c(y_c), \quad u_d \equiv 0$$

renders $\mathcal{A}$ globally pre-asymptotically stable.

In a similar manner, an output-feedback law can be designed when, instead of being flow-passive, $\mathcal{H}_P$ is jump-passive with respect to $\mathcal{A}$. In this case, if the storage function V is positive definite with respect to $\mathcal{A}$ and has compact sublevel sets, and if there exists a continuous function $\kappa_d : \mathbb{R}^{m_{P,d}} \rightarrow \mathbb{R}^{m_{P,d}}$, $y_d^\top \kappa_d(y_d) > 0$ for all $y_d \neq 0$, such that the resulting closed-loop system with $u_c \equiv 0$ and $u_d = -\kappa_d(y_d)$ has the following properties:

(PBC4) The distance to $\mathcal{A}$ is detectable relative to

$$\{z \in \Pi(C_P) \cup \Pi(D_P) \cup G_P(D_P) : h_d(z)^\top \kappa_d(h_d(z)) = 0, (z, -\kappa_d(h_d(z))) \in D_P\};$$

(PBC5) Every complete solution ϕ is Zeno;

then the the output-feedback law

$$u_d = -\kappa_d(y_d), \quad u_c \equiv 0$$

renders $\mathcal{A}$ globally pre-asymptotically stable. Such a feedback design can be employed to globally asymptotically stabilize the controlled bouncing ball in Example 1.

Strict passivity notions can also be formulated for hybrid plants, including the special cases where the power inequalities hold only during flows or jumps. In particular, strict passivity and output strict passivity can be employed to assert asymptotic stability with zero inputs.

Tracking Control Design

While numerous control problems pertain to the stabilization of a set-point condition, at times, it is desired to stabilize the solutions to the plant to a time-varying trajectory. In this section, we consider the problem of designing a hybrid

controller $\mathcal{H}_K$ for a hybrid plant $\mathcal{H}_P$ to track a given reference trajectory r (a hybrid arc). The notion of tracking is introduced below. We propose sufficient conditions that general hybrid plants and controllers should satisfy to solve such a problem. For simplicity, we consider tracking of state trajectories and that the hybrid controller can measure both the state of the plant z and the reference trajectory r ; hence, $v = (z, r)$.

The particular approach used here consists of recasting the tracking control problem as a set stabilization problem for the closed-loop system $\mathcal{H}$. To do this, we embed the reference trajectory r into an augmented hybrid model for which it is possible to define a set capturing the condition that the plant tracks the given reference trajectory. This set is referred to as *the tracking set*. More precisely, given a reference $r : \text{dom } r \rightarrow \mathbb{R}^{n_P}$, we define the set $\mathcal{T}_r$ collecting all of the points (t, j) in the domain of r at which r jumps, that is, every point $(t_j^-, j) \in \text{dom } r$ such that $(t_j^-, j+1) \in \text{dom } r$. Then, the state of the closed loop $\mathcal{H}$ is augmented by the addition of states $\tau \in \mathbb{R}_{\geq 0}$ and $k \in \mathbb{N}$. The dynamics of the states τ and k are such that τ counts elapsed flow time, while k counts the number of jumps of $\mathcal{H}$; hence, during flows $\dot{\tau} = 1$ and $\dot{k} = 0$, while at jumps $\tau^+ = \tau$ and $k^+ = k + 1$. These new states are used to parameterize the given reference trajectory r , which is employed in the definition of the tracking set:

$$\mathcal{A} = \{(z, \eta, \tau, k) \in \mathbb{R}^{n_P} \times \mathbb{R}^{n_K} \times \mathbb{R}_{\geq 0} \times \mathbb{N} : z = r(\tau, k), \eta \in \Phi_K\} \quad (14)$$

This set is the target set to be stabilized for $\mathcal{H}$. The set $\Phi_K \subset \mathbb{R}^{n_K}$ in the definition of $\mathcal{A}$ is some closed set capturing the set of points asymptotically approached by the state of the controller η .

Using results to certify pre-asymptotic stability of closed sets for hybrid systems, sufficient conditions guaranteeing that a hybrid controller $\mathcal{H}_K$ stabilizes the tracking set $\mathcal{A}$ in (14) for the hybrid closed-loop system $\mathcal{H}$ can be formulated. In particular, with $\mathcal{H}$ having state $x = (z, \eta, \tau, k)$ and data

$$\begin{aligned}
C &= \{x : (z, \kappa_c(\eta, z, r(\tau, k))) \in C_P, \tau \in [t_k^r, t_{k+1}^r], (\eta, z, r(\tau, k)) \in C_K\} \\
F(z, \eta, \tau, k) &= (F_P(z, \kappa_c(\eta, z, r(\tau, k))), F_K(\eta, z, r(\tau, k)), 1, 0) \\
D &= \{x : (z, \kappa_c(\eta, z, r(\tau, k))) \in D_P, (\tau, k) \in \mathcal{T}_r\} \cup \\
&\quad \{x : \tau \in [t_k^r, t_{k+1}^r), (\eta, z, r(\tau, k)) \in D_K\} \\
G_1(z, \eta, \tau, k) &= (G_P(z, \kappa_c(\eta, z, r(\tau, k))), \eta, \tau, k + 1), \\
G_2(z, \eta, \tau, k) &= (z, G_K(\eta, z, r(\tau, k)), \tau, k)
\end{aligned}$$

given a complete reference trajectory $r : \text{dom } r \rightarrow \mathbb{R}^{n_P}$ and associated tracking set $\mathcal{A}$, a hybrid controller $\mathcal{H}_K$ with data $(C_K, F_K, D_K, G_K, \kappa)$ guaranteeing that

- (T1) The jumps of r and $\mathcal{H}_P$ occur simultaneously;
(T2) For some continuously differentiable function $V : \mathbb{R}^{n_P} \times \mathbb{R}^{n_K} \times \mathbb{R}_{\geq 0} \times \mathbb{N} \rightarrow \mathbb{R}$, functions $\alpha_1, \alpha_2 \in \mathcal{K}_\infty$; and continuous, positive definite functions ρ_1, ρ_2, ρ_3 , the following hold:

- (T2a) For all $(z, \eta, \tau, k) \in C \cup D \cup G_1(D) \cup G_2(D)$

$$\begin{aligned}
\alpha_1(|(z, \eta, \tau, k)|_{\mathcal{A}}) &\leq V(z, \eta, \tau, k) \leq \\
&\alpha_2(|(z, \eta, \tau, k)|_{\mathcal{A}})
\end{aligned}$$

- (T2b) For all $(z, \eta, \tau, k) \in C$ and all $\zeta \in F(z, \eta, \tau, k)$,

$$\langle \nabla V(z, \eta, \tau, k), \zeta \rangle \leq -\rho_1(|(z, \eta, \tau, k)|_{\mathcal{A}})$$

- (T2c) For all $(z, \eta, \tau, k) \in D_1$ and all $\zeta \in G_1(z, \eta, \tau, k)$

$$V(\zeta) - V(z, \eta, \tau, k) \leq -\rho_2(|(z, \eta, \tau, k)|_{\mathcal{A}})$$

- (T2d) For all $(z, \eta, \tau, k) \in D_2$ and all $\zeta \in G_2(z, \eta, \tau, k)$

$$V(\zeta) - V(z, \eta, \tau, k) \leq -\rho_3(|(z, \eta, \tau, k)|_{\mathcal{A}})$$

renders $\mathcal{A}$ is globally pre-asymptotically stable for $\mathcal{H}$.

Note that condition (T1) imposes that the jumps of the plant and of the reference trajectory occur simultaneously. Though restrictive, at

times, this property can be enforced by proper design of the controller.

Forward Invariance-Based Control Design

As defined in section “[Definitions and Notions](#)”, a set K is forward invariant if every solution to the system from K stays in K . Also known as *flow-invariance*, *positively invariance*, *viability*, or just *invariance*, this property is very important in feedback control design. In fact, asymptotically stabilizing feedback laws induce forward invariance of the set $\mathcal{A}$ that is asymptotically stabilized. Forward invariance is also key to guarantee safety properties, since safety can be typically recast as forward invariance of the set that excludes every point (and, for robustness, a neighborhood of it) for which the system is considered to be unsafe. In this section, forward invariance (or, equivalently, safety) is guaranteed by infinitesimal conditions that involve functions of the state known as barrier functions.

Given a hybrid closed-loop system $\mathcal{H} = (C, F, D, G)$, a function $B : \mathbb{R}^n \rightarrow \mathbb{R}$ is a *barrier function candidate* defining a set $K \subset C \cup D$ if

$$K = \{x \in C \cup D : B(x) \leq 0\} \quad (15)$$

In some settings, the set K might be given a priori and then one would seek for a barrier function B such that (15) holds; namely, find a function B that is nonpositive at points in K only. In some other settings, one may generate the set K from the given sets C, D and the given function B .

A function candidate B is a *barrier function* if, in addition, its change along every solution ϕ to $\mathcal{H}$ that starts from K is such that

$$(t, j) \mapsto B(x(t, j))$$

is nonpositive. One way to guarantee such property is as follows. Given a hybrid system $\mathcal{H} = (C, F, D, G)$, suppose the barrier function candidate B defines a closed K as in (15). Furthermore, suppose B is continuously differentiable. Then, B is said to be a barrier function if, for some $\rho > 0$,

$$\begin{aligned} \langle \nabla B(x), \xi \rangle &\leq 0 \quad \forall x \in ((K + \rho\mathbb{B}) \setminus K) \cap C, \\ \forall \xi &\in F(x) \cap T_C(x) \end{aligned} \quad (16)$$

$$B(\xi) \leq 0 \quad \forall \xi \in G(D \cap K) \quad (17)$$

$$G(D \cap K) \subset C \cup D \quad (18)$$

The barrier function notion introduced above for $\mathcal{H}$ can be formulated for a hybrid plant $\mathcal{H}_P$ given as in (1). In such a setting, since the input to $\mathcal{H}_P$ is not yet assigned, the conditions in (16), (17), and (18) would depend on the input – similar to the conditions that control Lyapunov functions in section “CLF-Based Control Design” have to satisfy. Such an extension is illustrated in the next example for the bouncing ball system, which, since the input only affects the jumps, conditions (17) and (18) become

$$\begin{aligned} \forall z \in \Pi(D_P) \exists u_d \text{ such that } (z, u_d) \in D_P \text{ and} \\ \begin{cases} B(\xi) \leq 0 & \forall \xi \in G_P(z, u_d) \\ G_P(z, u_d) \subset \Pi(C_P) \cup \Pi(D_P) \end{cases} \end{aligned} \quad (19)$$

Example 4 (controlled bouncing ball revisited) Consider the problem of keeping the total energy of the juggling system in Example 1 less than or equal to a constant $V^* \geq 0$. The total energy of the hybrid plant therein is given by

$$V(z) = \gamma z_1 + \frac{1}{2} z_2^2$$

Then, the desired set K to render invariant is defined by the continuously differentiable barrier candidate

$$B(z) := V(z) - V^* \quad \forall z \in \mathbb{R}^2$$

In fact, for the case of a hybrid plant, the set K in (15) collects all points in $z \in \Pi(C_P) \cup \Pi(D_P)$

such that $V(z) \leq V^*$. It follows that

$$\langle \nabla B(z), F_P(z) \rangle = 0 \quad \forall z \in \Pi(C_P)$$

since, during flows, the total energy remains constant. At jumps, the following hold – recall that $u_d = u$: for each $z \in \Pi(D_P) = \{z \in \mathbb{R}^2 : z_1 = 0, z_2 \leq 0\}$,

$$G_P(z, u) = \begin{bmatrix} 0 \\ u \end{bmatrix}$$

and

$$\begin{aligned} B(G_P(z, u)) &= V(G_P(z, u)) - V^* \\ &= \gamma z_1 + \frac{1}{2} u^2 - V^* = \frac{1}{2} u^2 - V^* \end{aligned}$$

Hence, for B to be a barrier function, for each $z \in \Pi(D_P)$, we pick u to satisfy

$$|u| \leq \sqrt{2V^*}$$

In this way, any state feedback $z \mapsto \kappa_d(z)$ such that $|\kappa_d(z)| \leq \sqrt{2V^*}$ for each $z \in \Pi(D_P)$ leads to a hybrid closed-loop system with K forward invariant (It is easy to show that every maximal solution to such a closed loop is complete.). Note that assigning u to a feedback that is positive (when possible) leads to solutions that, after a jump, flow for some time.

Temporal Logic

Design specifications for control design typically include requirements that go beyond asymptotic stability properties, such as finite-time properties and safety constraints, some of which need to be satisfied at specific times rather than in the limit. A framework suitable for handling such specifications is linear temporal logic (LTL). LTL permits the formulation of desired properties such as *safety*, or equivalently, “something bad never happens,” and *liveness*, namely, “something good eventually happens” in finite time.

In LTL, a formula (or sentence) is given in terms of atomic propositions that are combined using Boolean and temporal operators. An atomic

proposition is a function of the state that, for each possible value of the state, is either true or false. More precisely, for $\mathcal{H}$ in (7), a proposition α is such that $\alpha(x)$ is either **True** (1 or $\top$) or **False** (0 or $\perp$). Boolean operators include the following: $\neg$ is the *negation* operator; $\vee$ is the *disjunction* operator; $\wedge$ is the *conjunction* operator; $\Rightarrow$ is the *implication* operator; and $\Leftrightarrow$ is the *equivalence* operator. A way to reason about a solution defined over hybrid time is needed to introduce temporal operators. This is defined by the semantics of LTL, as follows.

Given a solution ϕ to $\mathcal{H}$, a proposition α being **True** at $(t, j) \in \text{dom } \phi$ is denoted by

$$\phi(t, j) \models \alpha$$

If α is **False** at $(t, j) \in \text{dom } \phi$, then we write

$$\phi(t, j) \not\models \alpha$$

Similarly, given an LTL formula f , we say that it is satisfied by ϕ at (t, j) if

$$(\phi, (t, j)) \models f$$

while f not being satisfied at (t, j) is denoted by

$$(\phi, (t, j)) \not\models f$$

The temporal operators are defined as follows: with α and $\mathbf{b}$ being two atomic propositions

- $\bigcirc$ is the *next* operator: $(\phi, (t, j)) \models \bigcirc \alpha$ if and only if

$$(t, j+1) \in \text{dom } \phi \text{ and } (\phi, (t, j+1)) \models \alpha$$

- $\diamond$ is the *eventually* operator: there exists $(t', j') \in \text{dom } \phi$, $t' + j' \geq t + j$ such that $(\phi, (t', j')) \models \alpha$

- $\square$ is the *always* operator: $(\phi, (t, j)) \models \square \alpha$ if and only if, for each $t' + j' \geq t + j$, $(t', j') \in \text{dom } \phi$,

$$(\phi, (t', j')) \models \alpha$$

- $\mathcal{U}_s$ is the strong *until* operator: $(\phi, (t, j)) \models \alpha \mathcal{U}_s \mathbf{b}$ if and only if there exists $(t', j') \in \text{dom } \phi$, $t' + j' \geq t + j$, such that

$$(\phi, (t', j')) \models \mathbf{b}$$

and for all $(t'', j'') \in \text{dom } \phi$ such that $t + j \leq t'' + j'' < t' + j'$,

$$(\phi, (t'', j'')) \models \alpha$$

- $\mathcal{U}_w$ is the weak *until* operator: $(\phi, (t, j)) \models \alpha \mathcal{U}_w \mathbf{b}$ if and only if either

$$(\phi, (t', j')) \models \alpha$$

for all $(t', j') \in \text{dom } \phi$ such that $t' + j' \geq t + j$, or

$$(\phi, (t, j)) \models \alpha \mathcal{U}_s \mathbf{b}$$

Similar semantics apply to a formula f .

Example 5 (Thermostat system revisited) Consider the thermostat system in Example 2. Suppose that the goal is to keep the temperature within the range $[z_{\min}, z_{\max}]$ when the temperature starts in that region, and when it does not start from that range, steer it to that range in finite time and, after that, remain in that range for all time. For simplicity, suppose that the second input is constant and given by $u_2 \equiv z_{\text{out}}$, with $z_{\text{out}} \in (-\infty, z_{\max}]$ and $z_{\text{out}} + z_{\Delta} \in [z_{\min}, \infty)$. It can be shown that the following hybrid controller $\mathcal{H}_K$ accomplishes the state goal: with $\eta \in \{0, 1\}$, and with dynamics

$$\mathcal{H}_K : \begin{cases} \dot{\eta} \in F_K(\eta, v) := 0 & (\eta, v) \in C_K := (\{0\} \times C_{K,0}) \cup (\{1\} \times C_{K,1}) \\ \eta^+ \in G_K(\eta, v) := 1 - \eta & (\eta, v) \in D_K := (\{0\} \times D_{K,0}) \cup (\{1\} \times D_{K,1}) \\ \zeta = \kappa(\eta, v) := \eta \end{cases} \quad (20)$$

where

$$C_{K,0} := \{v : v \geq z_{\min}\},$$

$$C_{K,1} := \{v : v \leq z_{\max}\}$$

$$D_{K,0} := \{v : v \leq z_{\min}\},$$

$$D_{K,1} := \{v : v \geq z_{\max}\}$$

The input of the controller is assigned via $v = z$ and its output assigned u via $u = \zeta = \eta$. Furthermore, it can be shown that the hybrid closed-loop system satisfies the following LTL formulae: with

$$\begin{aligned} \alpha(z, \eta) &= 1 & \text{if } z \in [z_{\min}, z_{\max}], \\ \alpha(z, \eta) &= 0 & \text{if } z \notin [z_{\min}, z_{\max}], \end{aligned}$$

the following hold:

- $\Box a$ for every solution with initial temperature in $[z_{\min}, z_{\max}]$, regardless of the initial value of η .
- $\Diamond a$, $\Diamond \Box a$, and $\Box \Diamond a$ for every solution.

Sufficient conditions involving Lyapunov functions for finite-time attractivity and barrier functions can be employed to guarantee that certain formulas are satisfied. The following table provides pointers to such results (Table 1).

Summary and Future Directions

Advances over the last decade on modeling and robust stability of hybrid dynamical systems (without control inputs) have paved the road for the development of systematic methods for the design of control algorithms for hybrid plants. The results selected for this short expository entry, along with recent efforts on multi-mode/logic-based control, event-based control, and backstepping, which were not covered here, are scheduled to appear. Future research

Hybrid Dynamical Systems, Feedback Control of, Table 1 Sufficient conditions for LTL formulas involving temporal operators $\Box$, $\Diamond$, $\mathcal{U}_s$, and $\mathcal{U}_w$

f	Sufficient conditions in the literature
$\Box a$	Properties of the data of $\mathcal{H}$ – (Han and Sanfelice 2018, Sections 4.3 and 5.3)
$\Box a$	Forward invariance – Chai and Sanfelice (2019), Maghenem and Sanfelice (2018), and (Han and Sanfelice 2018, Section 5.1)
$\Diamond a$	Finite-time attractivity – Li and Sanfelice (2019) and (Han and Sanfelice 2018, Section 5.2)
$\alpha \mathcal{U}_s b$	Forward invariance and finite-time attractivity – (Han and Sanfelice 2018, Section 5.4)
$\alpha \mathcal{U}_w b$	Forward invariance or finite-time attractivity – (Han and Sanfelice 2018, Section 5.4)

directions include the development of more powerful tracking control design methods, state observers, and optimal controllers for hybrid plants.

Hybrid Model Predictive Control

Ricardo G. Sanfelice
Department of Electrical and Computer Engineering, University of California, Santa Cruz, CA, USA

Abstract

Model predictive control is a powerful technique to solve problems with constraints and optimality requirements. Hybrid model predictive control further expands its capabilities by allowing for the combination of continuous-valued with discrete-valued states, and continuous dynamics with discrete dynamics or switching. This short article summarizes techniques available in the literature addressing different aspects of hybrid MPC, including those for discrete-time piecewise affine systems, discrete-time mixed logical dynamical systems, linear systems with periodic impulses, and hybrid dynamical systems.

control and the environment, MPC strategies determine the value of the control inputs to apply by solving an optimization problem over a finite time horizon. The system to control, which is known as the *plant*, is typically given by a state-space model with state, input, and outputs. Most MPC strategies **measure** the output of the plant and, using a mathematical model of the plant, **predict** the possible values of the state and the output in terms of free input variables to be determined. The prediction is performed over a *prediction horizon* which is defined as a finite time interval in the future. With such parameterized values of the state and input over the prediction horizon, MPC **solves** an optimization problem. To formulate the optimization control problem (OCP), a cost functional is to be defined. The OCP can also incorporate constraints, such as those on the state, the input, and the outputs of the plant. Then, MPC **selects** an input signal that solves the OCP and **applies** it to the plant for a finite amount of time, which is defined by the *control horizon*. After the input is applied over the control horizon, the process is repeated.

Over the past two decades, MPC has emerged as one of the preferred planning and control engines in robotics and control applications. Such grown interest in MPC has been propelled by recent advances in computing and optimization, which have led to significantly smaller computation times in the solution to certain optimization problems. However, the complexity of the dynamics, constraints, and control objectives in the MPC has increased so as to accommodate the specifics of the applications of interest. In particular, the dynamics of the system to control might substantially change over the region of operation, the constraints or the control objectives may abruptly change upon certain self-triggered or externally-triggered events, and the optimization problems may involve continuous-valued and discrete-valued variables. MPC problems with such features have been studied in the literature under the name *hybrid model predictive control* (Sanfelice 2018). Within a common framework and notation, this entry summarizes

several hybrid MPC approaches available in the literature.

Notation and Preliminaries

Notation

The set of nonnegative integers is denoted as $\mathbb{N} := \{0, 1, 2, \dots\}$ and the set of positive integers as $\mathbb{N}_{>0} := \{1, 2, \dots\}$. Given $N \in \mathbb{N}_{>0}$, we define $\mathbb{N}_{<N} := \{0, 1, 2, \dots, N-1\}$ and $\mathbb{N}_{\leq N} := \{0, 1, 2, \dots, N\}$. The set of real numbers is denoted $\mathbb{R}$ and, given $n \in \mathbb{N}_{>0}$, $\mathbb{R}^n$ is the n -dimensional Euclidean space. The set of nonnegative real numbers is $\mathbb{R}_{\geq 0} := [0, \infty)$ and the set of positive real numbers is denoted as $\mathbb{R}_{>0} := (0, \infty)$. Given $x \in \mathbb{R}^n$, $|x|$ denotes its Euclidean norm and given $p \in [1, \infty]$, $|x|_p$ denotes its p -norm.

Discrete-Time, Continuous-Time, and Hybrid Systems

A general nonlinear discrete-time system takes the form

$$x^+ = f(x, u) \quad (1)$$

$$y = h(x, u) \quad (2)$$

where x is the state, u the input, and y the output. The symbol $^+$ on x is to indicate, when a solution to the system is computed, the new value of the state after each discrete-time step. The parameter $k \in \mathbb{N}$ denotes discrete time. Given an input signal $\mathbb{N} \ni k \mapsto u(k)$, the solution to (1) is given by the function $\mathbb{N} \ni k \mapsto x(k)$ that satisfies

$$x(k+1) = f(x(k), u(k)) \quad \forall k \in \mathbb{N}$$

Similarly, the output associated to this solution is given by

$$y(k) = h(x(k), u(k)) \quad \forall k \in \mathbb{N}$$

A general nonlinear continuous-time system takes the form

$$\dot{x} = f(x, u) \quad (3)$$

$$y = h(x, u) \quad (4)$$

where x is the state, u the input, and y the output. The dot on x is to indicate the change of x with respect to ordinary time. The parameter t denotes continuous time. Given an input signal $\mathbb{R}_{\geq 0} \ni t \mapsto u(t)$, a solution to (3) is given by a function $\mathbb{R}_{\geq 0} \ni t \mapsto x(t)$ that is regular enough to satisfy

$$\frac{d}{dt}x(t) = f(x(t), u(t))$$

at least for almost all $t \in \mathbb{R}_{\geq 0}$. The output associated to this solution is given by

$$y(t) = h(x(t), u(t)) \quad \forall t \in \mathbb{R}_{\geq 0}$$

A hybrid dynamical system takes the form

$$\mathcal{H} : \begin{cases} \dot{x} = F(x, u) & (x, u) \in C \\ x^+ = G(x, u) & (x, u) \in D \end{cases} \quad (5)$$

where x is the state and u the input. The set C defines the set of points in the state and input space from which flows are possible according to the differential equation $\dot{x} = F(x, u)$. The function F is called the flow map. The set D defines the set of points in the state and input space from where jumps are possible according to the difference equation $x^+ = G(x, u)$. The function G is called the jump map. Similar to the model for continuous-time systems in (3) and (4), the dot on x is to indicate the change of x with respect to ordinary time. Ordinary time is denoted by the parameter t , which takes values from $\mathbb{R}_{\geq 0}$. As a difference to the model for discrete-time systems in (1) and (2), the symbol $^+$ on x denotes the new value of the state after a jump is triggered. Every time that a jump occurs, the discrete counter j is incremented by one. A solution to the hybrid system can flow or jump, according to the values of the state and of the input relative to C and D , respectively. Solutions to $\mathcal{H}$ are parameterized by t and j , and are defined on hybrid time domains. The hybrid time domain of a solution x is denoted $\text{dom } x$, which is a subset of $\mathbb{R}_{\geq 0} \times \mathbb{N}$ and has the following structure: there exists a real nondecreasing

sequence $\{t_j\}_{j=0}^J$ with $t_0 = 0$, and when J is finite, $t_{J+1} \in [t_J, \infty]$ such that $\text{dom } x = \bigcup_{j=0}^J I_j \times \{j\}$. Here, $I_j = [t_j, t_{j+1}]$ for all $j < J$. If J is finite, I_{J+1} can take the form $[t_J, t_{J+1}]$ (when $t_{J+1} < \infty$), or possibly $[t_J, t_{J+1})$. It is convenient to consider the solution and the input as a pair (x, u) defined on the same hybrid time domain, namely, $\text{dom}(x, u) = \text{dom } x = \text{dom } u$. Given an input signal $(t, j) \mapsto u(t, j)$, a function $(t, j) \mapsto x(t, j)$ is a solution to the hybrid system if, over intervals of flow, it is locally absolutely continuous and satisfies

$$\frac{d}{dt}x(t, j) = F(x(t, j), u(t, j))$$

when

$$(x(t, j), u(t, j)) \in C$$

and, at jump times, it satisfies

$$x(t, j+1) = G(x(t, j), u(t, j))$$

when

$$(x(t, j), u(t, j)) \in D$$

Hybrid Model Predictive Control Strategies

Most MPC strategies in the literature are for plants given in terms of discrete-time models of the form $x^+ = f(x, u)$, where x is the state and u is the input. In particular, the case of f being linear has been widely studied and documented ► [Model Predictive Control in Practice](#). The cases in which the function f is discontinuous, or when either x or u have continuous-valued and discrete-value components require special treatment. In the literature, such cases are referred to as *hybrid*: either the system or the MPC strategy are said to be hybrid. Another use of the term hybrid is when the control algorithm obtained from MPC is nonsmooth, e.g., when the MPC strategy selects a control law from a family or when the MPC strategy is implemented using sample and hold. Finally, the term hybrid has been also employed in the literature to indicate that the plant exhibits state jumps at certain events. In such settings,

the plant is modeled by the combination of continuous dynamics and discrete dynamics. In this section, after introducing basic definitions and notions, we present hybrid MPC strategies in the literature, starting from those that are for purely discrete-time systems (albeit with nonsmooth right-hand side) and ending at those for systems that are hybrid due to the combination of continuous and discrete dynamics.

MPC for Discrete-Time Piecewise Affine Systems

Piecewise affine (PWA) systems in discrete time take the form

$$x^+ = A_i x + B_i u + f_i \quad (6)$$

$$y = C_i x + D_i u \quad (7)$$

$$\text{subject to } x \in \Omega_i, u \in \mathcal{U}_i(x), i \in S \quad (8)$$

where x is the state, u the input, and y the output. The origin of (6), (7), and (8) is typically assumed to be an equilibrium state for zero input u . The set $S := \{1, 2, \dots, \bar{s}\}$ with $\bar{s} \in \mathbb{N}_{>0}$ is a finite set to index the different values of the matrices and constraints. For each $i \in S$, the constant matrices $(A_i, B_i, f_i, C_i, D_i)$ define the dynamics of x and the output y . The elements f_i of the collection is such that $f_i = 0$ for all $i \in S$ such that $0 \in \Omega_i$. For each $i \in S$, the state constraints are determined by Ω_i and the state-dependent input constraints by $\mathcal{U}_i(x)$. The collection $\{\Omega_i\}_{i=1}^{\bar{s}}$ is a collection of polyhedra such that

$$\bigcup_{i \in S} \Omega_i = \mathcal{X}$$

where $\mathcal{X} \subset \mathbb{R}^n$ is the region of operation of interest. Moreover, the polyhedra are typically such that their interiors do not intersect, namely,

$$\text{int}(\Omega_i) \cap \text{int}(\Omega_j) = \emptyset \quad \forall i, j \in S : i \neq j$$

For each $x \in \Omega_i$, the set $\mathcal{U}_i(x)$ defines the allowed values for the input u .

For this class of systems, an MPC strategy consists of

1. At the current state of the plant, solve the OCP over a discrete prediction horizon;
2. Apply the optimal control input over a discrete control horizon;
3. Repeat.

The OCP associated to this strategy is as follows: given

- the current state x_0 of (6), (7), and (8),
- a prediction horizon $N \in \mathbb{N}_{>0}$,
- a terminal constraint set $\mathcal{X}_f$,
- a stage cost $\mathcal{L}$, and
- a terminal cost $\mathcal{F}$

the MPC problem consists of minimizing the cost functional

$$\mathcal{J}(x, i, u) := \sum_{k=0}^{N-1} \mathcal{L}(x(k), i(k), u(k)) + \mathcal{F}(x(N))$$

over solutions $k \mapsto x(k)$, indices sequence $k \mapsto i(k)$, and inputs $k \mapsto u(k)$ subject to

$$x(0) = x_0 \quad (9)$$

$$x(N) \in \mathcal{X}_f \quad (10)$$

$$\forall k \in \mathbb{N}_{<N} : \quad x(k+1) = A_{i(k)}x(k) + B_{i(k)}u(k) + f_{i(k)} \quad (11)$$

$$\forall k \in \mathbb{N}_{\leq N} : \quad y(k) = C_{i(k)}x(k) + D_{i(k)}u(k) \quad (12)$$

$$x(k) \in \Omega_{i(k)} \quad (13)$$

$$u(k) \in \mathcal{U}_{i(k)}(x(k)) \quad (14)$$

$$i(k) \in S \quad (15)$$

A few observations about the OCP above are in order. The solution $k \mapsto x(k)$ is uniquely defined by x_0 and $k \mapsto (i(k), u(k))$. The condition in (9) imposes the initial condition for the solution $k \mapsto x(k)$, while (10) restricts the value of x at the end of the prediction horizon. The condition in (11) is to enforce that $k \mapsto x(k)$ is a solution for the input $k \mapsto u(k)$. Similarly, (12) imposes that an output is generated according to the dynamics of the PWA system in (6), (7), and (8). The conditions in (13) and (14) enforce the state and (state-dependent) input constraints associated with the PWA system. Finally, (15) forces the indexing signal $k \mapsto i(k)$ to belong to the finite set of possible indices S . Typical choices of the functions $\mathcal{L}$ and $\mathcal{F}$ in the cost functional $\mathcal{J}$ are

$$\begin{aligned}\mathcal{L}(x, i, u) &:= |Q_i x|_p + |R_i u|_p, \\ \mathcal{F}(x) &:= |P x|_p\end{aligned}$$

for some $p \in [1, \infty]$, where, for each $i \in S$, Q_i and R_i and P are matrices of appropriate dimensions.

Further Reading

For key properties of the MPC problem for PWA systems in this section, the reader is referred to Lazar et al. (2006). In particular, sufficient conditions for recursive feasibility and asymptotic stability of the origin of the PWA system appeared in Lazar et al. (2006, Theorem III.2). In that reference, the reader can also find insight on how to select the terminal cost and the terminal constraint set; see Lazar et al. (2006, Section IV and Section V). The same reference also provides insight on how to solve the OCP using off-the-shelf tools. Very importantly, when $p = 1$ or $p = \infty$, the OCP can be rewritten as a mixed integer linear program (MILP). Furthermore, when the stage and terminal costs are quadratic, the OCP can be rewritten as a mixed integer quadratic program (MIQP).

MPC for Discrete-Time Systems with Continuous and Discrete-Valued States

Mixed Logical Dynamical (MLD) systems are discrete-time systems involving states, inputs,

and outputs that have continuous-valued and discrete-valued components. MLD systems are given by

$$x^+ = Ax + B_1 u + B_2 \delta + B_3 z + B_4 \quad (16)$$

$$y = Cx + D_1 u + D_2 \delta + D_3 z + D_4 \quad (17)$$

$$\text{subject to } E_2 \delta + E_3 z \leq E_1 u + E_4 x + E_5 \quad (18)$$

where x is the state, u the input, y the output, z continuous-valued auxiliary variables, and δ discrete-valued auxiliary variables. The state, the input, and the output have continuous-valued and discrete-valued components; for example, certain components take values from Euclidean spaces while others from discrete sets, like $\{0, 1\}$. The partition of the state x is typically given by $x = (x_c, x_\ell)$, with x_c being the continuous-valued components and x_ℓ the discrete-valued components of x ; similarly for the input $u = (u_c, u_\ell)$ and for the output $y = (y_c, y_\ell)$. The matrices A , $\{B_i\}_{i=1}^3$, B_4 , C , $\{D_i\}_{i=1}^3$, and D_4 define the dynamics of x and the output y . The matrices $\{E_i\}_{i=1}^5$ are used in (18) to define constraints coupling the continuous-valued and discrete-valued states. The latter matrices can be properly defined to recast constraints into properties of discrete-valued states. For instance, when $x \in [-x_{\max}, x_{\max}]$ with $x_{\max} \geq 0$, the constraint $x \geq 0$ is equivalent to $\delta = 1$ (and, in turn, $x < 0$ is equivalent to $\delta = 0$) when, for some $\varepsilon > 0$, the following inequalities hold:

$$x_{\max} \delta \leq x + x_{\max}, \quad -(x_{\max} + \varepsilon) \delta \leq -x - \varepsilon \quad (19)$$

This constraint can be written as (18) with $E_1 = 0$, $E_2 = [x_{\max} \quad -(x_{\max} + \varepsilon)]^\top$, $E_3 = 0$, $E_4 = [1 \quad -1]^\top$, and $E_5 = [x_{\max} \quad \varepsilon]^\top$.

For this class of systems, the MPC strategy in section “[MPC for Discrete-Time Piecewise Affine Systems](#)” is typically employed, and the OCP associated to it is as follows: given

- the current state x_0 of (16), (17), and (18),
- a prediction horizon $N \in \mathbb{N}_{>0}$,

- a terminal constraint set $\mathcal{X}_f$,
- a stage cost $\mathcal{L}$, and
- a terminal cost $\mathcal{F}$

$$\mathcal{J}(x, z, \delta, u)$$

the MPC problem consists of minimizing the cost functional

over solutions $k \mapsto x(k)$, auxiliary variables $k \mapsto z(k)$ and $k \mapsto \delta(k)$, and inputs $k \mapsto u(k)$ subject to

$$x(0) = x_0 \quad (20)$$

$$x(N) \in \mathcal{X}_f \quad (21)$$

$$\forall k \in \mathbb{N}_{<N} : \quad x(k+1) = Ax(k) + B_1u(k) + B_2\delta(k) + B_3z(k) + B_4 \quad (22)$$

$$\forall k \in \mathbb{N}_{\leq N} : \quad y(k) = Cx(k) + D_1u(k) + D_2\delta(k) + D_3z(k) + D_4 \quad (23)$$

$$E_2\delta(k) + E_3z(k) \leq E_1u(k) + E_4x(k) + E_5 \quad (24)$$

H

A particular choice of the cost functional $\mathcal{J}$ used in the MLD literature is

$$\begin{aligned} \mathcal{J}(x, z, \delta, u) = & \sum_{k=0}^{N-1} \mathcal{L}(x(k), z(k), \delta(k), u(k)) \\ & + \mathcal{F}(x(N)) \end{aligned}$$

where the stage and terminal costs are given by

$$\begin{aligned} \mathcal{L}(x, z, \delta, u) := & |Qx|_p + |Q_z z|_p \\ & + |Q_\delta \delta|_p + |Ru|_p, \\ \mathcal{F}(x) := & |Px|_p \end{aligned}$$

for some $p \in [1, \infty]$ and constant matrices Q , R , Q_δ , and Q_z of appropriate dimension.

Further Reading

Chapter 18 of Borrelli et al. (2017) provides a detailed presentation of MPC for MLD systems as in (16), (17), and (18). Following the ideas in recasting state constraints using discrete-valued auxiliary states as in (19), the MPC problem for MLD systems is formulated therein as mixed integer (linear and quadratic) problems. Previous articles about MLD systems include Bemporad et al. (2000a,b, 2002), Lazar et al. (2006), and Borrelli et al. (2017). Mixed-integer optimization methods were also used in Karaman et al. (2008) to solve feasibility and optimization

problems for MLD systems with temporal logic specifications.

Periodic MPC for Continuous-Time Systems

MPC can be directly applied to plants given by continuous-time nonlinear systems modeled as in (3) and (4), without discretization of the dynamics. The price to pay is that the optimal control input has to be determined over a finite-time window of continuous time. An MPC strategy for such systems consists of:

1. At the current state of the plant, solve the OCP over a continuous-time prediction horizon;
2. Apply the optimal control input over a continuous-time control horizon;
3. Repeat.

The OCP to solve is as follows: given

- the current state x_0 of (3),
- a prediction horizon $T \in \mathbb{R}_{>0}$,
- a terminal constraint set $\mathcal{X}_f$,
- a stage cost $\mathcal{L}$, and
- a terminal cost $\mathcal{F}$

minimize the cost functional

$$\mathcal{J}(x, u) := \int_0^T \mathcal{L}(x(t), u(t))dt + \mathcal{F}(x(T))$$

over solutions $t \mapsto x(t)$ and inputs $t \mapsto u(t)$ subject to

$$x(0) = x_0 \quad (25)$$

$$x(T) \in \mathcal{X}_f \quad (26)$$

$$\forall t \in (0, T) : \frac{d}{dt}x(t) = f(x(t), u(t)) \quad (27)$$

$$\forall t \in [0, T] : y(t) = h(x(t), u(t)) \quad (28)$$

$$u(t) \in \mathcal{U} \quad (29)$$

Typically, the right-hand side f is assumed to be twice continuously differentiable to assure uniqueness of solutions. Furthermore, the zero state is typically assumed to be an equilibrium point for (3) with zero input. The input constraint set, which is denoted by $\mathcal{U}$, is commonly assumed to be compact and convex, and to have the property that the origin belongs to its interior.

Further Reading

One of the first articles on MPC for continuous-time systems is Mayne and Michalska (1990). A reference that is more closely related to the MPC algorithm presented in this section is Chen and Allgöwer (1998). The approach in this article is to select the terminal constraint set $\mathcal{X}_f$ as a forward invariant neighborhood of the origin. The invariance-inducing feedback law is taken to be linear. In Chen and Allgöwer (1998), a method to design the feedback, the terminal constraint set, and the terminal cost is provided. Due to their design approach leading to a cost functional that upper bounds the cost of the associated infinite horizon control problem, the MPC strategy in Chen and Allgöwer (1998) is called quasi-infinite horizon nonlinear MPC. While the work in Chen and Allgöwer (1998) allows for general piecewise continuous inputs as candidates for the optimal control, the particular case studied in Magni and Scattolini (2004) considers only piecewise-constant functions that change values periodically. The algorithm in the latter reference results in a type of sample-and-hold MPC strategy. Similar ideas were employed in Nešić

and Grüne (2006) for the purposes of finding a sampled version of a continuous-time controller via MPC.

MPC for Linear Systems with Periodic Impulses

Linear systems with periodic impulses on the state are given by

$$\dot{x}(t) = Ax(t) \quad \forall t \in (k\delta, (k+1)\delta] \quad (30)$$

$$x(t^+) = x(t) + Bu_k \quad \forall t = k\delta \quad (31)$$

for each $k \in \mathbb{N}$, where $t \mapsto x(t)$ is a left-continuous function and, for each impulse time, namely, each $t \in \{0, \delta, 2\delta, \dots\}$, $x(t^+)$ is the right limit of $x(t)$. Similarly to the MPC strategies presented in the earlier sections, an output can be attached to the model in (30) and (31). The constant $\delta > 0$ is the sampling period, and u_k is the constant input applied at the impulse time $t = k\delta$. As shown in the literature, the sequence of constant inputs $\{u_k\}_{k \in \mathbb{N}}$ can be determined using the following MPC strategy: for each $k \in \mathbb{N}$,

1. At the current state of the plant at $t = k\delta$, solve the OCP over a prediction horizon including $N - 1$ future impulse times;
2. Apply the first entry of the optimal input to the plant until the next impulse time.

The OCP to solve is as follows: given

- the current state x_0 of (30) and (31),
- a prediction horizon $N \in \mathbb{N}_{>0}$,
- a terminal constraint set $\mathcal{X}_f$, and
- a stage cost $\mathcal{L}$

minimize the cost functional

$$\mathcal{J}(x, u) = \sum_{k=0}^{N-1} \mathcal{L}(x(\tau_k), u(\tau_k))$$

over the value of the solutions and inputs at the impulse times, which are denoted as $x(k)$ and $u(k)$, respectively, subject to

$$x(0) = x_0 \quad (32)$$

$$x(N\delta) \in \mathcal{X}_f \quad (33)$$

$$\forall k \in \mathbb{N}_{<N} : \quad \dot{x}(t) = Ax(t) \quad \forall t \in (k\delta, (k+1)\delta] \quad (34)$$

$$x(t^+) = x(t) + Bu(t) \quad \forall t = k\delta \quad (35)$$

$$x(t) \in \mathcal{X} \quad \forall t \in [k\delta, (k+1)\delta] \quad (36)$$

$$u(\tau_k) \in \mathcal{U} \quad (37)$$

The cost functional given above is a particular choice used in the literature, which does not include a terminal cost. The set $\mathcal{X}$ denotes the state constraints and the set $\mathcal{U}$ the input constraints.

Further Reading

The formulation above is based on Sopasakis et al. (2015). The developments therein further exploit the periodicity of the setting and employ the fact that the solutions to the system in (30) and (31) can be directly obtained at the impulse times from the computation of the solutions to the discrete-time system $x^+ = \exp(A\delta)(x + Bu)$. In addition, Sopasakis et al. (2015) employs over approximation techniques with the goal of reducing the number of constraints associated with the OCP above. For this purpose, polytopic over-approximations of the continuous dynamics of the impulsive system are proposed therein so as to arrive at a convex quadratic program. It should be pointed out that the stability concept used in Sopasakis et al. (2015) is weak in the sense that closeness and convergence of the values of the solution are only required to occur at the impulse times. Due to the combination of features of impulsive systems and of sample-data systems, the MPC strategy in Sopasakis et al. (2015) is one of the MPC approaches found in the literature that is closest to hybrid dynamical systems, as introduced in the next section.

MPC for Hybrid Dynamical Systems

Hybrid dynamical systems are systems with state variables that are allowed to evolve continuously and, at times, jump. A mathematical model of a hybrid system, denoted $\mathcal{H}$, was given in (5). This model is general enough to capture the

main features of other hybrid system modeling formalisms. For the purposes of MPC, it should be noted that the flow set C and the jump set D in (5) can already accommodate state and input constraints. Furthermore, compared to the MPC strategies for discrete-time systems and for continuous-time systems introduced earlier, the fact that hybrid systems have solution pairs (x, u) defined on a hybrid time domain $\text{dom}(x, u)$, which is parameterized by ordinary time t and jump time j , requires a prediction horizon that includes both prediction of ordinary time and of jump times. One such prediction horizon is given by the set

$$\mathcal{T} := \{(t, j) \in \mathbb{R}_{\geq 0} \times \mathbb{N} : \max\{t/\delta, j\} = \tau\} \quad (38)$$

for a positive integer τ and some positive constant δ . These parameters determine the “length” of $\mathcal{T}$ and the step size during flow for prediction. With this construction, the OCP to solve in an MPC strategy for hybrid systems will require that the terminal time, which now will be given by a pair (T, J) , satisfies $\max\{T/\delta, J\} = \tau$. A hybrid control horizon, parameterized by a positive integer $\tau_c < \tau$ and positive constant $\delta_c < \delta$, with the same structure as the prediction horizon is defined.

With such a horizon structure, an MPC strategy for a plant modeled as a hybrid dynamical system $\mathcal{H}$ is as follows:

- (1) At the current state of the plant, solve the OCP over the hybrid prediction horizon;
- (2) Apply the optimal hybrid input to the plant over the hybrid control horizon;
- (3) Repeat.

The OCP to solve as part of this MPC strategy is as follows: given

- the current state x_0 of (5),
- prediction horizon parameters $\tau \in \mathbb{N}_{>0}$ and $\delta > 0$,
- control horizon parameters $\tau_c \in \mathbb{N}_{<\tau} \setminus \{0\}$ and $\delta_c \in (0, \delta)$,
- a terminal constraint set $\mathcal{X}_f$,
- stage costs $\mathcal{L}_C$ and $\mathcal{L}_D$, and
- a terminal cost $\mathcal{F}$

the MPC problem consists of minimizing the cost functional

$$\begin{aligned} \mathcal{J}(x, u) := & \left(\sum_{j=0}^J \int_{t_j}^{t_{j+1}} \mathcal{L}_C(x(t, j), u(t, j)) dt \right) \\ & + \left(\sum_{j=0}^{J-1} \mathcal{L}_D(x(t_{j+1}, j), u(t_{j+1}, j)) \right) \\ & + \mathcal{F}(x(T, J)) \end{aligned}$$

over solution pairs $(t, j) \mapsto (x(t, j), u(t, j))$ with hybrid time domain that is a compact subset of $[0, T] \times \mathbb{N}_{\leq J}$, subject to

$$x(0, 0) = x_0 \quad (39)$$

$$(T, J) \in \mathcal{T} \quad (40)$$

$$x(T, J) \in \mathcal{X}_f \quad (41)$$

$$\begin{aligned} \forall j \in \mathbb{N} \text{ with } \text{int}(I_j) \neq \emptyset : \quad & \frac{d}{dt}x(t, j) = F(x(t, j), u(t, j)) \quad (x(t, j), u(t, j)) \in C \\ & \text{for almost all } t \in I_j, \quad (42) \end{aligned}$$

$$\forall (t, j) \in \text{dom } x \text{ s.t. } (t, j+1) \in \text{dom } x : \quad x(t, j+1) = G(x(t, j), u(t, j)) \quad (x(t, j), u(t, j)) \in D \quad (43)$$

where (T, J) denotes the terminal time of the solution pair (x, u) and $\{t_j\}_{j=0}^{J+1}$ is the sequence defining $\text{dom}(x, u)$, with $t_{J+1} = T$. The function $\mathcal{L}_C$ defines the cost of flowing on the flow set C and the function $\mathcal{L}_D$ defined the cost of jumping from the jump set.

Further Reading

For more details about the MPC strategy for hybrid dynamical systems presented in this section, the reader is referred to Altin et al. (2018) and Altin and Sanfelice (2019). The case when the hybrid dynamics are discretized is treated in Ojaghi et al. (2019). It should be noted that when the flow and jump sets overlap, the OCP may have multiple optimal inputs. Nonuniqueness of optimal inputs already appears in nonlinear MPC (see, e.g., in Grimm et al. 2007; Rawlings and Mayne 2009; Borrelli et al. 2017; Mayne and Michalska 1990; Chen and Allgöwer 1997; Magni and Scattolini 2004),

but the source of nonuniqueness of solutions for the case of hybrid dynamical systems is conceptually different. For these systems, conditions guaranteeing that the value function, which at every point x_0 is given by $\mathcal{J}^*(x_0) := \mathcal{J}(x_*, u_*)$ with (x_*, u_*) being minimizers of $\mathcal{J}$ from x_0 , implies an asymptotic stability property for the plant are given in Altin and Sanfelice (2019). The same reference also highlights key properties of the feasibility set, recursive feasibility, monotonicity properties of the cost functional, and regularity properties of the value function.

Abstract

In first part two hybrid observer designs for non-hybrid systems are presented. In the second part, recently results available in the literature related to the observability and observer design for different classes of hybrid systems are introduced.

Keywords

Hybrid systems · Observer design ·
Observability · Switching systems

Introduction

Observers' design, which are used to estimate the unmeasured plant state, has received a lot of attention since the late 1960s. One of the first leading contributions to clearly formalize the estimation problem and propose a solution in the linear case has been introduced by Luenberger (1966). The recipe to implement a Luenberger-type observer for linear time-invariant (LTI) continuous-time systems described by

$$\dot{x} = Ax + Bu, \quad y = Cx + Du, \quad (1)$$

with $x \in \mathbb{R}^n, u \in \mathbb{R}^p, y \in \mathbb{R}^m, A \in \mathbb{R}^{n \times n}, B \in \mathbb{R}^{n \times p}, C \in \mathbb{R}^{m \times n}$, and $D \in \mathbb{R}^{m \times p}$ has three main ingredients: system data (A, B, C, D) , the correction term commonly referred to as *output injection*, and the *observability/detectability/determinability* conditions. A Luenberger-type observer for (1) is then a copy of the system dynamics with the output injection term $\mathbf{L}(y - \hat{y})$ as

$$\dot{\hat{x}} = A\hat{x} + Bu + \mathbf{L}(y - \hat{y}), \quad \hat{y} = C\hat{x} + Du, \quad (2)$$

with $\mathbf{L} \in \mathbb{R}^{n \times m}$ and where $\hat{x}$ is the estimated value of x . Certainly if $\hat{x}(0) = x(0)$ and the input to the plant $u(t)$ is known, then $\hat{x}(t) = x(t)$ for all $t \geq 0$. For all nontrivial cases, when $x(0) \neq \hat{x}(0)$, the estimation error defined as $e = x - \hat{x}$ satisfies the differential equation $\dot{e} = (A - LC)e$, with initial condition $e(0) = x(0) - \hat{x}(0)$. The time evolution of the estimation error $e(t)$ depends only on the properties of the matrix $A + LC$, i.e., if the pair (A, C) is observable (equivalent to determinability for continuous-time systems), there exists a unique $\mathbf{L}$ to assign arbitrarily the eigenvalues of $A + LC$ with negative real part to render the origin $e = 0$ of the estimation error system globally asymptotically stable (GAS). If the pair (A, C) is detectable, there exists $\mathbf{L}$ such that all the eigenvalues of $A + LC$ still have negative real parts ensuring that the origin $e = 0$ is GAS, although all the eigenvalues cannot be arbitrarily chosen. The observer (2) exploits only the injection term $\mathbf{L}$ in continuous time to render Hurwitz the matrix $A + LC$, but one may ask how profitable could be to allow jumps of the observer state designing an observer that has both continuous (flow map) and discrete (jump map) time dynamics, i.e., an *hybrid observer*. On the other way around, there are systems that are intrinsically described by hybrid dynamics and for which it seems natural to directly provide hybrid observers. Designs of hybrid observer is a relatively new area of research, and results are consolidated only for few classes of systems.

In section “[Continuous-Time Plants](#),” a hybrid redesign of the observer (2) is discussed first, and then a more general design for nonlinear systems

is introduced, whereas in section “[Systems with Flows and Jumps](#),” the recent results related to observability and observer designs for hybrid systems are discussed. Conclusions are given in section “[Summary and Future Directions](#).”

Hybrid Observers: Different Strategies

The community of researchers working on hybrid observer, which is a quite recent area and is the subject of growing interest, is wide, and a unique formal definition/notation has not been reached yet. This fact is strictly related to the large number of different hybrid system models that are currently adopted by researchers. To render as simple as possible this short presentation, we let the state $x(t)$ of a hybrid system be driven by the flow map (differential equation) when $t \neq t_j$ and by the jump map (difference equation) when $t = t_j$ is the jump time and $x(t)$ is right continuous, i.e., $\lim_{t \rightarrow t_j^+} x(t) = x(t_j)$.

Continuous-Time Plants

Linear Case

A simple strategy to improve convergence to zero of the estimation error for (1) has been proposed in Raff and Allgower (2008) and consists in resetting the observer state $\hat{x}$, at predetermined fixed jump times t_j , by means of the linear correction term $\mathbf{K}(t)(y(t) - C\hat{x}(t))$ as

$$\dot{\hat{x}}(t) = A\hat{x}(t) + Bu(t) + \mathbf{L}(y(t) - C\hat{x}(t)), \quad (3a)$$

$$\hat{x}(t_j) = \hat{x}(t_j^-) + \mathbf{K}(t_j^-)(y(t_j^-) - C\hat{x}(t_j^-)), \quad (3b)$$

where $t_0 = 0$, $t_{j+1} - t_j = T > 0$, $j \in \mathbb{N}_{\geq 1}$ and T is a parameter that defines the interval times between resets and has to be chosen such that

$$\text{Im}(\lambda_p - \lambda_r)T \neq 2r\pi, \quad r \in \mathbb{Z} \setminus \{0\}, \quad (4)$$

for each pair (λ_p, λ_r) of complex eigenvalues of the matrix $A - LC$. This selection preserves the (continuous time or flow) observability of the system (1) when sampled at time instants t_j . Then, the estimation error $e(t)$ converges to zero in finite time, $t = nT$, if (1) is observable and the matrix $K(t) : \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}^{n \times m}$ is selected such as $K(t) = K_0$ if $t \leq t_n$ and $K(t) = 0$ otherwise where K_0 is such that $(I - K_0 C) \exp((A - LC)T)$ has all its eigenvalues at zero. It is important to note that the state reset (3b) yields a hybrid estimation error system given by

$$\dot{e}(t) = (A - LC)e(t), \quad (5a)$$

$$e(t_j) = (I - K(t_j^-)C)e(t_j^-). \quad (5b)$$

The stability property of the origin can be easily deduced by noting that

$$e(t_j) = \prod_{k=1}^j (I - K(t_k^-)C) \exp((A - LC)T)e(0),$$

and given that $(I - K_0 C) \exp((A - LC)T)$ is nilpotent, then $e(t_n) = e(nT) = 0$.

Along the same line, to improve convergence performances of continuous-time observer, in Prieur et al. (2012), it is proposed a methodology to limit the well-known *peaking phenomena* affecting the *high-gain observers* (Tornambé 1992; Khalil and Praly 2013) opportunely resetting its (augmented) state. Moreover, when the output of (1) is a nonlinear function of the state, $y = h(x)$, with $h(\cdot)$ not invertible (e.g., the saturation function), it would be possible to rewrite (1) as a hybrid system with linear flow map and augmented state designing a hybrid observer as in Carnevale and Astolfi (2009). In Possieri and Teel (2016), an introduction to structural properties for estimation and output feedback stabilization of linear hybrid systems is given.

Nonlinear Case

When the input of a continuous-time plant is piecewise-constant, the hybrid observer proposed in Moraal and Grizzle (1995), exploiting sampled measurements, can be successfully applied for a class of nonlinear continuous (or discrete-time) systems

$$\dot{x} = f(x(t), u(t)), \quad y(t) = h(x(t), u(t)), \quad (6)$$

with sufficiently smooth maps $f(\cdot, \cdot)$ and $h(\cdot, \cdot)$ and where

$$x(t_j) = F(x(t_{j-1}), u(t_{j-1})), \quad (7)$$

is the sample data (discrete-time) version of (6) with sampling time $T = t_{j-1} - t_j$. Then, it is possible to define a hybrid observer of the following type:

$$\dot{\hat{x}}(t) = f(\hat{x}(t), u(t)), \quad (8a)$$

$$\hat{x}(t_j) = \Gamma(y(t_j^-), \hat{x}(t_j^-), \xi(t_j^-)), \quad (8b)$$

where the reset map Γ and the dynamics of the new variable $\xi(t)$ have to be properly defined. The main idea in Moraal and Grizzle (1995) is that the Newton method, in continuous and discrete-time, can be used to estimate the value of ξ that renders zero the function

$$W_j^N(\xi) = Y_j^N - H(\xi, U_j^N), \quad (9)$$

where $U_j^N = [u'(t_{j-N+1}), \dots, u'(t_j)]'$ and $Y_j^N = [y'(t_{j-N+1}), \dots, y'(t_j)]'$ are the sampled input and output vectors, respectively, and $H : \mathbb{R}^n \times \mathbb{R}^{m \times N} \rightarrow \mathbb{R}^N$ maps the state $x(t_j)$ and the N-tuple of control inputs U_j^N into the output vector Y_j^N , i.e., $H(x(t_j), U_j^N) = Y_j^N$, and is defined as

$$H(x, U_j^N) \triangleq \begin{bmatrix} h(F^{-1}(F^{-1}(\dots, u(t_{j-N+1})), u(t_{j-N+1}))) \\ \vdots \\ h(F^{-1}(x, u(t_{j-1})), u(t_{j-1})) \\ h(x, u(t_j)) \end{bmatrix}, \quad (10)$$

where F^{-1} shortly represents the inverse of the map F such that $x(t_{j-1}) = F^{-1}(x(t_j), u(t_{j-1}))$.

The system (6) and (7) is said to be *N-observable*, for some $N \geq 1$ (the generic selection is $N = 2n + 1$), when $W_j^N(\xi) = 0$ hold only if $\xi = x(t_j)$, uniformly in U_j^N . Then, under certain technical assumptions (see Moraal and Grizzle 1995) related to the derivatives of f and h and the invertibility of the Jacobian matrix $J(x) = \partial H(x)/\partial x$, it is possible to select

$$\dot{\xi}(t) = kJ(\xi(t))^{-1} (Y_j^N - H(\xi(t), U_j^N)), \quad (11a)$$

$$\xi(t_j) = F(\xi(t_j^-), u(t_{j-1})), \quad (11b)$$

with a sufficiently high-gain $k > 0$ and the reset map $\Gamma(\cdot) = F(\xi(t_j^-), u(t_{j-1}))$. Note that (11a) is commonly referred to as Newton flow. This approach could be easily extended to other continuous-time minimization algorithms (normalized gradient, line search, etc.) changing the rhs of (11a) or even with discrete-time methods iterated at higher frequency within the sample time T , yielding faster convergence to zero of the estimation error.

The same approach can be used when a continuous-time observer for (6) is considered in place of (8a) and the Newton-based resets can be used to possibly improve the performances. The continuous and discrete-time Newton algorithm require the knowledge of the jump map F to define (7), i.e., the exact discrete-time model of (6), and the Jacobian matrix $J(x) = \partial H(x)/\partial x$. An approach that does not require such knowledge is proposed in Biyik and Arcak (2006), where continuous-time filters and secant method allow to estimate (numerically) the map F and the Jacobian matrix, or in Sassano et al. (2011) where an *extremum-seeking*-based technique is considered.

A different approach to estimate the state of a continuous-time plant, Pursued, for example, in Ahrens and Khalil (2009) and Liu (1997), exploits switching output injections, letting the correction term $l_\sigma(\cdot)$ to switch among opportune values selected by a suitable definition (often derived by a Lyapunov-based proof) of the switching signal $\sigma(t)$. These switching gains allow to improve observer performances and robustness against measurement noise and model uncertainties.

Systems with Flows and Jumps

The classical notion of observability does not hold for hybrid systems. As an example, consider the autonomous linear hybrid system described by $\dot{x}(t) = Ax(t)$ and $x(t_j) = Jx(t_j^-)$ with

$$A = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}, \quad J = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{bmatrix}, \quad (12)$$

and $C = [0, 1, 0]$. Evidently the flow is not observable in the classic sense given that $\mathcal{O}_{\text{flow}} = [C', (CA)', (CA^2)']'$ is not full rank and the flow-unobservable subspace is $\ker(\mathcal{O}_{\text{flow}}) \triangleq \{x \in \mathbb{R}^3 : x_2 = x_3 = 0\}$. Nevertheless, in the first flow time interval $\tau = t_1 - t_0$, it is possible to estimate (e.g., in finite time using the observability Gramian matrix) the initial conditions $(x_2(t_0), x_3(t_0))$. Then when the first jump take place at time t_1 , thanks to the structure of the jump map J that resets the value of $x_3(t_1)$ with the flow-unobservable $x_1(t_1^-)$, it is possible to estimate in the next flow time interval the value of $x_1(t_1^-)$ so that the initial condition $x(t_0)$ can be completely determined. The hybrid observability matrix in this case has the following expression

$$\mathcal{O}_{\text{hybrid}} = [\mathcal{O}'_{\text{flow}}, (\mathcal{O}_{\text{flow}} J e^{AT_1})', (\mathcal{O}_{\text{flow}} (J e^{AT_2})^2)']'$$

and is full rank for all $T_j = t_j - t_{j-1}$ satisfying (4). Note that from a practical point of view, in this case the time interval that allows to reconstruct the complete state is $[t_0, t_1 + \epsilon)$ since the observer needs at least an ϵ time of the new measurements (after the first jump) to evaluate the full state $[\mathcal{O}'_{\text{flow}}, (\mathcal{O}_{\text{flow}} J e^{AT_1})', (\mathcal{O}_{\text{flow}} (J e^{AT_2})^2)']'$. This simple example suggests that (impulsive) hybrid systems might have a reacher notion of observability than the classical ones. These properties have been studied also for mechanical systems subject to non-smooth impacts in Martinelli et al. (2004), where a high-gain-like observer design has been proposed assuming the knowledge of the impact times t_i , no *Zeno* phenomena (no finite accumulation point for t_j 's), and a minimum *dwell-time*, $t_{j+1} - t_j \geq \delta > 0$. With the aforementioned assumptions and considering the more general class of hybrid system described by

$$\begin{aligned}\dot{x}(t) &= f(x, u), \\ x(t_j) &= g(x(t_j^-), u(t_j^-)),\end{aligned}\quad (13)$$

with $y = h(x, u)$, a frequent choice is to consider the hybrid observer of the form

$$\dot{\hat{x}}(t) = f(\hat{x}, u) + \mathbf{l}(y, \mathbf{x}, \mathbf{u}), \quad (14a)$$

$$\hat{x}(t_j) = g(\hat{x}(t_j^-), u(t_j^-)) + \mathbf{m}(\hat{\mathbf{x}}(t_j^-), \mathbf{u}(t_j^-)), \quad (14b)$$

with $\mathbf{l}(\cdot)$ and $\mathbf{m}(\cdot)$ that are zero when $\hat{x} = x$ rendering flow and jump-invariant the manifold $\hat{x} = x$ relying only on the correction term $\mathbf{l}(\cdot)$ ($\mathbf{m} \equiv 0$) in a high-gain-like design during the flow. The correction during the flow has to recover, within the minimum dwell-time δ , the worst deterioration of the estimation error induced by the jumps (if any) and the transients such that $\|e(t_{j+1})\| < \|e(t_j^-)\|$ or $V(e(t_{j+1})) < V(e(t_j^-))$ if a Lyapunov function is available. This type of observer design, with $m = 0$ and the linear choice $\mathbf{l}(y, \hat{x}, u) = L(y - M\hat{x})$, has been proposed in

Heemels et al. (2011) for *linear complementarity systems* (LCS) in the presence of state jumps induced by impulsive input. Therein, solutions of LCS are characterized by means of piecewise Bohl distributions, and the specially defined *well-posedness* and *low-index* properties, which combined with passivity-based arguments, allow to design a global hybrid observer with exponential convergence. A separation principle to design an output feedback controller is also proposed.

An interesting approach is pursued in Forni et al. (2003) where global output tracking results on a class of linear hybrid systems subject to impacts is introduced. Therein, the key ingredient is the definition of a “mirrored” tracking reference (a change of coordinate) that depends on the sequence of different jumps between the desired trajectory (a virtual bouncing ball) and the plant (the controlled ball). Exploiting this (time-varying) change of coordinates and assuming that the impact times are known, it is possible to define an estimation error that is not discontinuous even when the tracked ball has a bounce (state jump) and the plant does not. A time regularization is included in the model embedding a minimum dwell-time among jumps. In this way, it is possible to design a linear hybrid observer represented by (14b) with a linear (mirrored) term $\mathbf{l}(\cdot)$ and $\mathbf{m}(\cdot) \equiv 0$, proving (by standard quadratic Lyapunov functions) that the origin of the estimation error system is GES. In this case, the standard observability condition for the couple (A, C) is required.

Switching Systems and Hybrid Automata

Switching systems and hybrid automata have been the subject of intense study of many researchers in the last two decades. For these class of systems, there is a neat separation $x = [z, q]'$ among purely discrete-time state q (*switching signal or system mode*) and rest of the state z that generically can both flow and jump. The observability of the entire system is often divided into the problem of determining the switching signal q first and then z . The switching signal can be divided into

two categories: arbitrary (*universal problem*) or specific (*existential problems*) switchings.

In Vidal et al. (2003), the observability of autonomous linear switched systems with no state jump, minimum dwell-time, and unknown switching signal is analyzed. Necessary and sufficient observability conditions based on rank tests and output discontinuities detection strategies are given. Along the same line, the results are extended in Babaali and Pappas (2005) to nonautonomous switched systems with non-Zeno solutions and without the minimum dwell-time requirement, providing state z and mode q observability characterized by linear-algebraic conditions.

Luenberger-type observers with two distinct gain matrices L_1 and L_2 are proposed in the case of bimodal piecewise linear systems in Juloski et al. (2007) (where state jumps are considered), whereas recently in Tanwani et al. (2013), algebraic observability conditions and observer design are proposed for switched linear systems admitting state jumps with known switching signal (although some asynchronism between the observer and the plant switches is allowed). Results related to the observability of hybrid automata, which include switching systems, can be found in Balluchi et al. (2002) and the related references. Therein the *location observer* estimates first the system *current location* q , processing system input and output assuming that it is *current-location observable*, a property that is related to the system *current-location observation tree*. This graph is iteratively explored at each new input to determine the node associated to the current value of $q(t)$. Then, a linear (switched) Luenberger-type observer for the estimation of the state z , assuming minimum dwell-time and observability of each pair (A_q, C_q) , is proposed. A local separation principle have been proposed in Teel (2010).

Summary and Future Directions

Observer design and observability properties of general hybrid systems is an active field of research, and a number of different results have

been proposed by researchers. Results are based on different notations and definitions for hybrid systems. Efforts to provide a unified approach, in many cases considering the general framework for hybrid systems proposed in Goebel et al. (2009), are pursued by the scientific community to improve consistency and cohesion of the general results. Observer designs, observability properties, and separation principle are still open challenges for the scientific community.

Identification and Control of Cell Populations

Mustafa Khammash¹ and J. Lygeros²

¹Department of Biosystems Science and Engineering, Swiss Federal Institute of Technology at Zurich (ETHZ), Basel, Switzerland

²Automatic Control Laboratory, Swiss Federal Institute of Technology Zurich (ETHZ), Zurich, Switzerland

Abstract

We explore the problem of identification and control of living cell populations. We describe how de novo control systems can be interfaced with living cells and used to control their behavior. Using computer controlled light pulses in combination with a genetically encoded light-responsive module and a flow cytometer, we demonstrate how in silico feedback control can be configured to achieve precise and robust set point regulation of gene expression. We also outline how external control inputs can be used in experimental design to improve our understanding of the underlying biochemical processes.

variability · Population control · Stochastic biochemical reactions

Introduction

Control systems, particularly those that employ feedback strategies, have been used successfully in engineered systems for centuries. But natural feedback circuits evolved in living organisms much earlier, as they were needed for regulating the internal milieu of the early cells. Owing to modern genetic methods, engineered feedback control systems can now be used to control in real-time biological systems, much like they control any other process. The challenges of controlling living organisms are unique. To be successful, suitable sensors must be used to measure the output of a single cell (or a sample of cells in a population), actuators are needed to affect control action at the cellular level, and a controller that connects the two should be suitably designed. As a model-based approach is needed for effective control, methods for identification of models of cellular dynamics are also needed. In this entry, we give a brief overview of the problem of identification and control of living cells. We discuss the dynamic model that can be used, as well as the practical aspects of selecting sensor and actuators. The control systems can either be realized on a computer (in silico feedback) or through genetic manipulations (in vivo feedback). As an example, we describe how de novo control systems can be interfaced with living cells and used to control

their behavior. Using computer controlled light pulses in combination with a genetically encoded light-responsive module and a flow cytometer, we demonstrate how *in silico* feedback control can be configured to achieve precise and robust set point regulation of gene expression.

Dynamical Models of Cell Populations

In this entry, we focus on a model of an essential biological process: gene expression. The goal is to come up with a mathematical model for gene expression that can be used for model-based control. Due to cell variability, we will work with a model that describes the average concentration of the product of gene expression (the regulated variable). This allows us to use population measurements and treat them as measurements of the regulated variable. We refer the reader to the entry ► [Stochastic Description of Biochemical Networks](#) in this encyclopedia for more information on stochastic models of biochemical reaction networks. In this framework, the model consist of an N -vector stochastic process $X(t)$ describing the number of molecules of each chemical species of interest in a cell. Given the chemical reactions in which these species are involve, the mean, $E[X(t)]$, of $X(t)$ evolves according to deterministic equations described by

$$\dot{E}[X(t)] = SE[w(X(t))],$$

where S is an $N \times M$ matrix that describes the stoichiometry of the M reactions described in the model, while $w(\cdot)$ is an M -vector of propensity functions. The propensity functions reflect the rate of the reactions being modeled. When one considers elementary reactions (see ► [Stochastic Description of Biochemical Networks](#)), the propensity function of the i th reaction, $w_i(\cdot)$, is a quadratic function of the form $w_i(x) = a_i + b_i^T x + c_i x^T Q_i x$. Typically, w_i is either a constant: $w_i(x) = a$, a linear function of the form $w_i(x) = bx_j$ or a simple quadratic of the form $w_i(x) = cx_j^2$. Following the same procedure, similar dynamical models can be derived that describe the evolution of higher-order moments

(variances, covariances, third-order moments, etc.) of the stochastic process $X(t)$.

Identification of Cell Population Models

The model structure outlined above captures the fundamental information about the chemical reactions of interest. The model parameters that enter the functions $w_i(x)$ reflect the reaction rates, which are typically unknown. Moreover, these reaction rates often vary between different cells, because, for example, they depend on the local cell environment, or on unmodeled chemical species whose numbers differ from cell to cell (Swain et al. 2002). The combination of this extrinsic parameter variability with the intrinsic uncertainty of the stochastic process $X(t)$ makes the identification of the values of these parameters especially challenging.

To address this combination of intrinsic and extrinsic variabilities, one can compute the moments of the stochastic process $X(t)$ together with the cross moments of $X(t)$ and the extrinsic variability. In the process, the moments of the parametric uncertainty themselves become parameters of the extended system of ordinary differential equations and can, in principle, be identified from data. Even though doing so requires solving a challenging optimization problem, effective results can often be obtained by randomized optimization methods. For example, Zechner et al. (2012) presents the successful application of this approach to a complex model of the system regulating osmotic stress response in yeast.

When external signals are available, or when one would like to determine what species to measure when, such moment-based methods can also be used in experiment design. The aim here is to determine *a priori* which perturbation signals and which measurements will maximize the information on the underlying chemical process that can be extracted from experimental data, reducing the risk of conducting expensive but uninformative experiments. One can show that, given a tentative model for the biochemical process, the moments of the stochastic process $X(t)$ (and

cross $X(t)$ -parameter moments in the presence of extrinsic variability) can be used to approximate the Fischer information matrix and hence characterize the information that particular experiments contain about the model parameters; an approximation of the Fischer information based on the first two moments was derived in Komorowski et al. (2011) and an improved estimate using correction terms based on moments up to order 4 was derived in Ruess et al. (2013). Once an estimate of the Fischer information matrix is available, one can design experiments to maximize the information gained about the parameters of the model. The resulting optimization problem (over an appropriate parametrization of the space of possible experiments) is again challenging but can be approached by randomized optimization methods.

Control of Cell Populations

There are two control strategies that one can implement. The control systems can be realized on a computer, using real-time measurements from the cell population to be controlled. These cells must be equipped with actuators that respond to the computer signals that close the feedback loop. We will refer to this as *in silico feedback*. Alternatively, one can implement the sensors, actuators, and control system in the entirety within the machinery of the living cells. At least in principle, this can be achieved through genetic manipulation techniques that are common in synthetic biology. We shall refer to this type of control as *in vivo feedback*. Of course some combination of the two strategies can be envisioned. In vivo feedback is generally more difficult to implement, as it involves working within the noisy uncertain environment of the cell and requires implementations that are biochemical in nature. Such controllers will work autonomously and are heritable, which could prove advantageous in some applications. Moreover, coupled with intercellular signaling mechanisms such as quorum sensing, in vivo feedback may lead to tighter regulation (e.g., reduced variance) of the cell population. On the other hand, in silico controllers are much easier to program, debug,

and implement and can have much more complex dynamics that would be possible with in vivo controllers. However, in silico controllers require a setup that maintains contact with all the cells to be controlled and cannot independently control large numbers of such cells. In this entry we focus exclusively on in silico controllers.

The Actuator

There could be several ways to send actuating signals into living cells. One consists of chemical inducers that the cells respond to either through receptors outside the cell or through translocation of the inducer molecules across the cellular membrane. The chemical signal captured by these inducers is then transduced to affect gene expression. Another approach we will describe here is induction through light. There are several light systems that can be used. One of these includes a light-sensitive protein called phytochrome B (PhyB). When red light of wavelength 650 nm is shined on PhyB in the presence of phyco-cyanobilin (PCB) chromophore, it is activated. In this active state it binds to another protein Pif3 with high affinity forming PhyB-Pif3 complex. If then a far-red light (730 nm) is shined, PhyB is deactivated and it dissociates from Pif3. This can be exploited for controlling gene expression as follows: PhyB is fused to a GAL4 binding domain (GAL4BD), which then binds to DNA in a specific site just upstream of the gene of interest. Pif3 in turn is fused to a GAL4 activating domain (GAL4AD). Upon red light induction, Pif3-Gal4AD complex is recruited to PhyB, where Gal4AD acts as a transcription factor to initiate gene expression. After far-red light is shined, the dissociation of GAL4BD-PhyB complex with Pif3-Gal4AD means that Gal4AD no longer activates gene expression, and the gene is off. This way, one can control gene expression – at least in open loop.

The Sensor

To measure the output protein concentration in cell populations, a fluorescent protein tag is needed. This tag can be fused to the protein of interest, and the fluorescence intensity emanating from each cell is a direct measure of the protein concentration in that cell. There are several

technologies for measuring fluorescence of cell populations. While fluorimeters measure the overall intensity of a population, flow cytometry and microscopy can measure the fluorescence of each individual cell in a population sample at a given time. This provides a snapshot measurement of the probability density function of the protein across the population. Repeated measurements over time can be used as a basis for model identification (Fig. 1).

The Control System

Equipped with sensors, actuators, and a model identified with the methods outlined above one can proceed to design control algorithms to regulate the behavior of living cells. Even though moment equations lead to models that look like conventional ordinary differential

equations, from a control theory point of view, cell population systems offer a number of challenges. Biochemical processes, especially genetic regulation, are often very slow with time constants of the order of tens of minutes. This suggests that pure feedback control without some form of preview may be insufficient. Moreover, due to our incomplete understanding of the underlying biology, the available models are typically inaccurate, or even structurally wrong. Finally, the control signals are often unconventional; for example, for the light control system outlined above, experimental limitations imply that the system must be controlled using discrete light pulses, rather than continuous signals.

Fortunately advances in control theory allow one to effectively tackle most of these challenges. The availability of a model, for example, enables the use of model predictive control methods that

Identification and Control of Cell Populations, Fig. 1 Top figure: shows a yeast cell whose gene expression can be induced by light: red light turns on gene expression while far-red turns it off. Bottom figure: Each input light sequences can be applied to a culture of light responsive

yeast cells resulting in a corresponding gene expression pattern that is measured by flow cytometry. By applying multiple carefully chosen light input test sequences and looking at their corresponding gene expression patterns a dynamic model of gene expression can be identified

Identification and Control of Cell Populations, Fig. 2 Architecture of the closed-loop light control system. Cells are kept darkness until they are exposed to light pulse sequences from the in silico feedback controller. Cell culture samples are passed to the flow cytometer whose

output is fed back to the computer which implements a Kalman filter plus a Model Predictive Controller. The objective of the control is to have the mean gene expression level follow a desired set value

Identification and Control of Cell Populations, Fig. 3 Left panel: The closed-loop control strategy (orange) enables set point tracking, whereas an open-loop strategy (green) does not. Right panel: Four different experiments,

each with a different initial condition. Closed-loop control is turned on at time $t=0$ shows that tracking can be achieved regardless of initial condition. (See Miliadis et al. (2011))

introduce the necessary preview into the feedback process. The presence of unconventional inputs may make the resulting optimization problems difficult, but the slow dynamics work in our favor, providing time to search the space of possible input trajectories. Finally, the fundamental principle of feedback is often enough to deal with inaccurate models. Unlike systems biology applications where the goal is to develop a model that faithfully captures the biology, in population control applications even an inaccurate model is often enough to provide adequate closed-loop performance. Exploring these issues, Miliars-Argeitis et al. (2011) developed a feedback mechanism for genetic regulation using the light control system, based on an extended Kalman filter and a model predictive controller (Figs. 2 and 3). A related approach was taken in Uhlenendorf et al. (2012) to regulate the osmotic stress response in yeast, while Toettcher et al. (2011) develop what is effectively a PI controller for a faster cell signaling system.

Summary and Future Directions

The control of cell populations offers novel challenges and novel vistas for control engineering as well as for systems and synthetic biology. Using external input signals and experiment design methods, one can more effectively probe biological systems to force them to reveal their secrets. Regulating cell populations in a feedback manner opens new possibilities for biotechnology applications, among them the reliable and efficient production of antibiotics and biofuels using bacteria. Beyond biology, the control of populations is bound to find further applications in the control of large-scale, multi-agent systems, including those in transportation, demand response schemes in energy systems, crowd control in emergencies, and education.

Identification of Network Connected Systems

Michel Verhaegen

Delft Center for Systems and Control, Delft University, Delft, The Netherlands

Abstract

An overview of the identification of a large number of linear time invariant (LTI) dynamical system that are operating within a network is given. Compared to the well-established field of identifying LTI lumped parameter

systems, system identification of network systems has to deal with the usual large-scale dimensions and the topology of the network as well. A unified state space approach is presented where the parametrization of the network topology or the spatial nature of the network and the parametrization of the temporal properties is viewed as a parametrization of the structure of the system matrices in a large-scale state space model. Different parametrizations are reviewed as well as the consequences they may have on the computational challenges for estimating these parameters. Though the field of identification of network systems is in full expansion, this overview may highlight some directions for new developments within this field.

identification

Introduction

The developments in hardware technology such as micro-optical-electro-mechanical (MOEMS) systems, wireless networks, and distributed computational technology contribute to the advancement of large network-connected systems. Examples are platoons of car, 2D arrays of wave-front sensors of measuring the optical disturbance induced by turbulence in ground-based telescopes, flow control, shape control, etc.

Two major classes of system identification approaches have been developed much along the lines of lumped parameter systems but now often inspired by particular applications. The first approach is based on the input-output transfer functions describing the dynamic connections in the network. This approach employs dynamic signal flow diagrams, and typical applications are from biological or computer networks (Gonçalves and Warnick 2008; Gevers et al. 2019). This approach will be indicated as the *signal flow approach*. The

second is based on structured (large) state space models and are, e.g., developed in the scope of designing sparse and/or distributed controller (efficiently) for network-connected systems. The latter is, e.g., done in D'Andrea and Dullerud (2003), Massioni and Verhaegen (2009), and Rice and Verhaegen (2009), and typical application areas are automated highway systems, formation flying, cross-directional control in paper processing, micro-cantilever array control for massive parallel data storage, or lumped parameter approximations of partial differential equations (PDEs); see applications discussed in D'Andrea and Dullerud (2003). Due to its connection with control design, this approach will be indicated by the *control engineering approach*.

For system identification a number of relevant problems are discussed in this overview. First in section “[Two Modeling Paradigms for Network-Connected Systems](#),” the (graphical) modeling that characterizes both approaches is presented. Here we address for the signal flow approach the recent question about network identifiability. Further merits and problems with both approaches are discussed. Then section “[Parametrizing Spatial-Temporal Dynamics](#)” elaborates on the second approach and discusses a number of parametrizations imposing structure on the system matrices of an LTI state space model. Such parametrization often requires knowledge of the network topology, that is, how the local dynamical systems communicate with one another. The section starts with presenting the parametrization with full prior knowledge of the location of non-zero entries in the system matrices. This would allow to treat identification problem of the signal flow approach as well. Then more black box parametrizations for system matrices that are banded or system matrices in so-called decomposable (Massioni and Verhaegen 2009) or multilinear state space models (Rogers and Russell 2013) are discussed. A brief algorithmic overview for estimating the parameters in these large-scale state space models is given in section “[Numerical Methodologies](#)”. Here we mainly present subspace(-like) algorithms that allow to derive structural information like the

size of the blocks in banded matrices from data. As this field is fully emerging, we present in section “[Summary and Future Directions](#)” a few of the many possibilities for further research.

Two Modeling Paradigms for Network-Connected Systems

Graphical Representation

Networks are generally represented using the language of graph theory, with nodes and edges. Two examples of such graphs are illustrated in Fig. 1. The left-hand side (a) represents the format used in control engineering, such as in D’Andrea and Dullerud (2003), while the signal flow diagram as used, e.g., in Gevers et al. (2019), is represented on the right-hand side (b).

For the control engineering approach, the nodes represent the systems in the network, such as S_i for $i = 1, \dots, 3$ in Fig. 1a, and the edges are the signals. With signal flow diagrams, the reverse convention holds, with nodes representing the signals, such as y_i for $i = 1, \dots, 3$ in Fig. 1b, and the edges are the systems. The topology or the network connection is represented by the graph adjacency or graph Laplacian matrix. A slight generalization of this concept is the pattern matrix (Massioni 2015). Such a pattern matrix for the simple example in Fig. 1 determines the topology or the spatial “dynamics” of the networks via the indices

1, 2, 3 in the gray circles. Using this (spatial) numbering, the pattern matrix is defined as a zero matrix except for the ones in the location ij when there is arrow going from node j to node i (not considering the summing elements). For this simple example, the pattern matrix $\mathcal{P}$ equals:

$$\mathcal{P} = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{bmatrix}$$

The pattern matrix of an undirected graph with two-sided arrows on the edges is symmetric and allows two-way communication between the nodes.

The Signal Flow Versus the Control Engineering Approach

Though both graphical representations in Fig. 1 equivalently represent the same network of systems, these representations have led to distinct approaches for analyzing large-scale distributed systems.

Let in the signal flow diagram of Fig. 1b the systems be represented by their causal transfer functions $S_i(q)$ (with q the shift operator such that $qx(k) = x(k+1)$); then the *dynamic structure function* (Gonçalves and Warnick 2008) is denoted as:

$$\begin{bmatrix} y_1(k) \\ y_2(k) \\ y_3(k) \end{bmatrix} = \begin{bmatrix} 0 & S_1(q) & 0 \\ 0 & 0 & S_2(q) \\ S_3(q) & 0 & 0 \end{bmatrix} \begin{bmatrix} y_1(k) \\ y_2(k) \\ y_3(k) \end{bmatrix}$$

Identification of Network Connected Systems, Fig. 1

Two graphical representations of the same network connection of dynamic systems S_i for $i = 1, \dots, 3$. (a) The control engineering approach with the nodes representing the systems S_i with interconnecting signals depicted as edges. The small circles $\circ$ represent summing points, with

its output the sum of its input signals. (b) Signal flow diagram representation with the nodes representing the signals y_i for $i = 1, \dots, 3$ with interconnecting systems depicted as edges. The incoming signals to the nodes are summed. The arrows in both cases depicting the direction in which data is transferred

Identification of Network Connected Systems, Fig. 2 1D network with resp. R neighboring systems on left and right of the system at location $i+1$ in the network.

The intersystem communication as indicated by the state quantities $x_{\bullet}(k)$ is not observed

$$+ \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} u_1(k) + \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} v_1(k) \\ v_2(k) \end{bmatrix} \quad (1)$$

This can compactly be denoted (with the proper definition of corresponding vectors) as:

$$y(k) = G(q)y(k) + K(q)u(k) + w(k) \quad (2)$$

This dynamic structure function is used as the model representation of the signal flow diagrams in Gonçalves and Warnick (2008) and Gevers et al. (2019) and the many references therein. This modeling paradigm turned out to be very useful in addressing *identifiability* questions. Such as under what conditions of the network topology and availability of the node measurements can the causal transfer functions $G(q)$, $K(q)$ and the power spectrum of $w(k)$ be uniquely identified? Such “global” identifiability question is about the *network identifiability* or identifiability of transfer functions and not about structural identifiability of parameters in these transfer functions. A recent overview of network identifiability for the case that *all node variables in the network are measured* with possibly singularity of the power spectrum of $w(k)$ is given in Gevers et al. (2019). When it is possible to (globally) estimate the transfer functions $G(q)$, $K(q)$, it was remarked in Gevers et al. (2019) that then one can find as well the network topology as revealed by the zero pattern in these estimated global transfer functions. These nice results do not extend straightforwardly for the

case some of the node signals are missing. It should be remarked that such problems occur “naturally” in a control engineering analysis of network-connected systems as highlighted, e.g., in D’Andrea and Dullerud (2003). This advocates a state space approach.

In this overview such an approach is the indicated control engineering approach. We restrict its presentation to spatial-temporal dynamical systems with spatial dynamics specified on a regular spatial grid, such as on a line or rectangular. For generalizations on irregular grids, we refer, e.g., to Massioni (2015). On such regular grids, the index of a system in a node is specified by its coordinates in that p -dimensional grid. This results in the definition of p -D systems. An example of such a 1-D system without boundary conditions and only specifying the system indices for the sake of brevity in the nodes is illustrated in Fig. 2. The temporal dynamics may be specified by the order of the local (state space) model that represents the input-output behavior of a local (series of) node(s). The example illustrates that the nodes communicate their states, and hence all these quantities are missing.

On such regular spatial grids, we may have spatially invariant systems where all systems in the nodes are equal or spatially varying systems where the systems dynamics can vary over the nodes.

In this overview we focus mainly on the identification of spatial-temporal dynamical systems within the control engineering approach.

Parametrizing Spatial-Temporal Dynamics

A Priori Parametrization

Similar to many lumped parameter identification methods, the identification of a complex network system starts with the a priori parametrization of both the spatial and temporal dynamics. This is illustrated for the example in Fig. 1a using a state space framework. Let the system in node 1 be described by the local state space model:

$$\begin{aligned} x_1(k+1) &= A_1 x_1(k) + B_1 y_2(k) \\ y_1(k) &= C_1 x_1(k) + u_1(k) + v_1(k) \end{aligned} \quad (3)$$

In a similar way, we can model the other two local nodes. *Lifting* the state quantities to the global state vector $x(k) = [x_1(k)^T \ x_2(k)^T \ x_3(k)^T]^T$ and similarly for the global input $u(k) = u_1(k)$, for the global noise $v(k)$, and for the global output $y(k)$, we obtain the following (global) state space model:

$$\begin{aligned} x(k+1) &= \begin{bmatrix} A_1 & B_1 C_2 & 0 \\ 0 & A_2 & B_2 C_3 \\ B_3 C_1 & 0 & A_3 \end{bmatrix} x(k) \\ &+ \begin{bmatrix} 0 \\ 0 \\ B_3 \end{bmatrix} u(k) + \begin{bmatrix} 0 & B_1 \\ 0 & B_2 \\ B_3 & 0 \end{bmatrix} v(k) \\ y(k) &= \begin{bmatrix} C_1 & 0 & 0 \\ 0 & C_2 & 0 \\ 0 & 0 & C_3 \end{bmatrix} x(k) \\ &+ \begin{bmatrix} I \\ 0 \\ 0 \end{bmatrix} + \begin{bmatrix} I & 0 \\ 0 & I \\ 0 & I \end{bmatrix} v(k) \end{aligned} \quad (4)$$

This global state space model can be compactly denoted as:

$$\begin{aligned} x(k+1) &= \mathcal{A}x(k) + \mathcal{B}u(k) + \mathcal{H}v(k) \\ y(k) &= \mathcal{C}x(k) + \mathcal{D}u(k) + \mathcal{G}v(k) \end{aligned} \quad (5)$$

This approach outlined for this simple example can be used for complex network systems, in general resulting in a state vector of extreme

large dimensions and sparse system matrices. The determination of the sparsity pattern of this matrix, i.e., where there are non-zero matrix blocks, falls under the banner of the spatial parametrization. The temporal parametrization comprises both the fixing of the size of these non-zero matrix blocks and the determination of the non-zero entries in these matrices. For the simple three node examples in Fig. 1, the observer canonical form parametrization of each system (assumed to be SISO) will yield an affine parametrization of the global state space model in (5).

Sparse System Matrices of (5)

The example discussed in the previous subsection illustrates that the global system matrices of a network may be sparse. In this subsection we present two sparse parametrizations and their rationale as to what classes of complex networks they may represent.

Decomposable systems When identical dynamical systems are linked in a network and when a communication link exists, it is identical; then such networks can be described as decomposable systems (Massioni and Verhaegen 2009). Examples are formation flying with identical satellites. The global system matrices in (5) of a decomposable system belong to the class of decomposable matrices. This class is defined next.

Definition 1 (Massioni and Verhaegen 2009)

For a given pattern matrix $\mathcal{P} \in \mathbb{R}^{N_n \times N_n}$ and matrices $M_a, M_b \in \mathbb{R}^{n_\ell \times n_r}$, the class of decomposable matrices contain all matrices $\mathcal{M} \in \mathbb{R}^{n_\ell N_n \times n_r N_n}$ of the following form:

$$\mathcal{M} = I_n \otimes M_a + \mathcal{P} \otimes M_b \quad (6)$$

with $\otimes$ representing the Kronecker product.

For the parametrization of decomposable systems, it is only necessary to provide the pattern matrix and to parametrize the matrix pair (M_a, M_b) for each system matrix in (5). For extreme efficient controller synthesis methods for such systems, we refer to Massioni and Verhaegen (2009). A comment on the identifica-

tion methodology is made in section “[Numerical Methodologies](#).”

Extension of this parametrization are the so-called α -decomposable systems (Massioni 2014). With this generalization we now have α different systems, each having a decomposable form.

Banded or tri-diagonal system matrices The 1-D network depicted in Fig. 2 may result from the spatial discretization of a system governed via PDEs in one spatial dimension. An example is the series connection of mass spring systems as an approximation of a flexible beam (Liu 2015). Each of these local systems in a regular 1-D grid exchanges information that is in general not measured. When we consider exchange of the state vector of the left and right neighboring systems in Fig. 2 only, the system matrices in the global state space model become block tri-diagonal. When the additional assumption is made that the spatial dynamics are invariant, the system matrices further become block Toeplitz matrices.

This class of systems can also be extended to p -D systems where then the system matrices get multibanded sparse matrices. Such sparse matrices can often be made block tri-diagonal matrices by just permutation, e.g., using the Cuthill-McKee method (Cuthill and McKee 1969). When such permutation exists, such p -D systems may very well be approximated by systems with block tri-diagonal system matrices. A final class of system matrices that may very well be accurately approximated within this class is the class when the system matrices are exponentially spatially decaying (Haber and Verhaegen 2014).

Dense Data Sparse System Matrices of (5)

SSS Systems In D’Andrea and Dullerud (2003) a generic modeling framework was proposed for spatially interconnected dynamical systems. This class will again be explained for 1-D systems as depicted in Fig. 2 for the generalization that the unobservable quantities that represent the communication between the local systems also have spatial dynamics. It has been shown in Rice and Verhaegen (2009) that lifting such local

Identification of Network Connected Systems, Fig. 3

An autonomous 1-D spatial-temporal dynamic system consisting of three local nodes with spatial dynamics. The interacting signals $s_i^*(k)$ are unmeasurable and have spatial dynamics as represented by (7)

models into a global state space model like (5) as was done for the simple example in section “[A Priori Parametrization](#)”, the system matrices of that space model become so-called sequentially semi-separable (SSS) matrices. This lifting procedure and the resulting SSS matrix are shown for the simple autonomous case considered in Fig. 3 considering spatial varying dynamics. For the autonomous 1-D system in Fig. 3, the spatial-temporal dynamics of the i -th system is described as:

$$\begin{bmatrix} x_i(k+1) \\ s_{i+1}^r(k) \\ s_{i-1}^l(k) \end{bmatrix} = \begin{bmatrix} A_i & P_i & U_i \\ Q_i & R_i & 0 \\ V_i & 0 & W_i \end{bmatrix} \begin{bmatrix} x_i(k) \\ s_i^r(k) \\ s_i^l(k) \end{bmatrix} \quad (7)$$

The spatial-temporal dynamics for systems at nodes $i-1$ and $i+1$ are similar (with indices adapted) with the following constraints (for this simple case):

$$\begin{aligned} P_{i-1} &\equiv U_{i+1} \equiv Q_{i+1} \equiv R_{i+1} \equiv W_{i+1} \\ &\equiv R_{i-1} \equiv V_{i-1} \equiv W_{i-1} \equiv 0 \end{aligned}$$

Then the lifted state space model becomes:

$$\begin{aligned} \begin{bmatrix} x_{i-1}(k+1) \\ x_i(k+1) \\ x_{i+1}(k+1) \end{bmatrix} &= \begin{bmatrix} A_{i-1} & U_{i-1}V_i & U_{i-1}W_iV_{i+1} \\ P_iQ_{i-1} & A_i & U_iV_{i+1} \\ P_{i+1}R_iQ_{i-1} & P_{i+1}Q_i & A_{i+1} \end{bmatrix} \\ &\begin{bmatrix} x_{i-1}(k) \\ x_i(k) \\ x_{i+1}(k) \end{bmatrix} \end{aligned} \quad (8)$$

The system matrix of this autonomous system has the SSS structure. SSS systems are LTI systems of the form (5) with all system matrices having the SSS structure. This structure is defined for the spatially invariant case in Definition 2. For its generalization to the spatially varying case, we refer to Rice and Verhaegen (2009).

Definition 2 (Rice and Verhaegen 2009)

The matrix $\mathcal{A}$ is an SSS matrix when it is defined by its generator of seven matrices (P, R, Q, A, U, W, V) of resp. sizes $n \times r_2$, $r_2 \times r_2$, $r_2 \times n$, $n \times n$, $n \times r_1$, $r_1 \times r_1$, and $r_1 \times n$, in the following way:

$$\mathcal{A} = \begin{bmatrix} A & UV & UWV & UW^2V & UW^3V & UW^4V & UW^5V \\ PQ & A & UV & UWV & UW^2V & UW^3V & UW^4V \\ PRQ & PQ & A & UV & UWV & UW^2V & UW^3V \\ PR^2Q & PRQ & PQ & A & UV & UWV & UW^2V \\ PR^3Q & PR^2Q & PRQ & PQ & A & UV & UWV \\ PR^4Q & PR^3Q & PR^2Q & PRQ & PQ & A & UV \\ PR^5Q & PR^4Q & PR^3Q & PR^2Q & PRQ & PQ & A_s \end{bmatrix} \quad (9)$$

The generator of the SSS matrix is the (generally) small-dimensional matrices P, R, Q, A, U, W, V . Therefore parametrizing these matrices only makes the parametrization *sparse*, while the full matrices like $\mathcal{A}$ are dense. This explains the indication dense data sparse. Usually these dense matrices are never formed explicitly conducting all operations on the generators only (Rice and Verhaegen 2009).

What is particular about this matrix class is that all the corner matrix partitions above and below the block diagonal, two of which are depicted in (9), have low rank.

Matrix or multilinear state space models In multidimensional signal processing, the observations made are not vectors but multidimensional objects. For example, in imaging the recorded images are 2D objects that may be stored in matrices.

This motivated (Squin and Verhaegen 2019) to propose matrix state space models (MSSM) of the following form:

$$\begin{aligned} X(k+1) &= A_1 X(k) A_2^T + B_1 U(k) B_2^T \quad (10) \\ Y(k) &= C_1 X(k) C_2^T + V(k) \end{aligned}$$

Here the state, input, and output are given in matrix form by the matrices $X(k)$, $U(k)$, and $Y(k)$, resp. Each of these matrices is defined

on a grid, which for simplicity is taken in this overview as an $N \times N$ grid. If, for example, the entry of the output at one grid point is p , the size of the matrix $Y(k)$ is $Np \times N$. When vectorizing these matrix quantities, we get a global state space model like in (5) for $\mathcal{H}$ and $\mathcal{D}$ equal to zero, with the system matrices given by Kronecker products, such as:

$$\mathcal{A} = A_1 \otimes A_2$$

This approach can be generalized by considering higher Kronecker rank expressions of the system matrices, given, for example, for $\mathcal{A}$ as:

$$\mathcal{A} = \sum_{i=1}^{n_a} A_{1,i} \otimes A_{2,i} \quad (11)$$

Such expression is known to be able to approximate a given linear operator as highlighted, for example, in Bamieh and Filo (2018). Dynamical systems like (5) with its system matrices having the form as in (11) are called multilinear dynamical systems (MLDS) (Rogers and Russell 2013).

Numerical Methodologies

In this section we illustrate some of the numerical challenges related to the three classes of model parametrizations discussed in the previous sec-

tion. This is done by highlighting one representative solution for each class.

Prediction Error Methods for a Prior Parametrized Models

Having parametrized the global model (5) via the parameter vector θ that include the characterization of the noise term $v(k)$, one can propose a predictor $\hat{y}(k, \theta)$ of the output. To find a “best” estimate of θ , a prediction error cost function can be defined as:

$$J(\theta) = \frac{1}{N_t} \sum_{k=1}^{N_t} \|y(k) - \hat{y}(k, \theta)\|^2 \quad (12)$$

where N_t data points are considered. The solution of this optimization problem in the signal flow framework with parametrization of the dynamic structure function in (1) is followed in Materassi and Salapaka (2012) and Dankers et al. (2016). The latter paper discusses the topic of predictor input selection to exploit the given structure in the dynamic structure function for reducing the computational complexity. However for large-scale networks, this approach remains extremely complex.

When abiding to the state space approach, one is challenged with the identifiability of the parameter vector θ used to parametrize the system matrices. This can be dealt with a priori by analyzing the structural identifiability of the parameters as, e.g., done in van den Hof (2002) or taken care about during the calculations by including a regularization term in the cost function (12). The latter is demonstrated in sparse Bayesian estimation using the expectation maximization algorithm in Yue et al. (2018) for a very specific measurement scenario considering the following matrices in (5):

$$C = [I \ 0] \quad D = 0 \quad H v(k) = \sigma e(k)$$

$$\mathcal{G}v(k) = e(k)$$

for $\sigma \in \mathbb{R}_+$ and $e(k)$ Gaussian zero-mean white noise with identity covariance matrix. An interesting though preliminary development to bridge the two approaches outlined in section “[The Signal Flow Versus the Control](#)

[Engineering Approach](#)” is also outlined in Yue et al. (2018). For the specific case, the transfer function $K(q)$ in (2) is square and diagonal; a parametrization of the system matrices $\mathcal{A}, \mathcal{B}$ in the state space model (5) has been proposed that makes the corresponding underlying dynamic structure function model network identifiable. However such exchange of features between signal flow approach and control engineering approach does not hold in general. For example, it was remarked in Yue et al. (2018) that the sparsity of the state space model in (5) does not mean that the transfer functions in the dynamic structure function (1) are sparse.

One attempt to reduce the computational burden in prediction error methods (PEM) is via the sparse parametrization of SSS system matrices, as done in Rice and Verhaegen (2011). However apart from the possible reduction in computational cost, PEM for large-scale systems suffer in general from the drawbacks of getting initial estimates, local minima, etc. This is because for the large-scale case, no generic subspace methodology is yet available that can be used to provide initial estimates as done for the identification of small-dimensional LTI systems.

To overcome the computational burden of estimating all parameters at once, an important research activity is to try to split up the global cost function in independent parts, each trying to identify a local system in the network. This research activity requires knowledge of the network topology. Some preliminary results for the signal flow approach can be found in Weerts et al. (2019). Here the methodology called “abstraction of linear dynamic networks” is presented to remove unknown signals that influence local models by replacing these unknown signals by signals calculated from measured signals so to enable the identification of the local models.

Subspace Identification for Sparse Network Models

Different attempts have been made to extend important advantages of subspace identification to network-connected systems. One such extension is in Yu and Verhaegen (2018). This method allows to identify the classes of sparse networks

as defined in the section “[Sparse System Matrices of \(5\)](#)” by solving a series of local identification problems. Though overcoming the computational challenge in this way, the system identification challenge becomes that we have to deal with the missing information about the interaction between the different local systems as well as block sizes of the matrices in, e.g., the block tri-diagonal parametrization. This information is extracted from the data as is characteristic for subspace methods.

The main steps of the approach in Yu and Verhaegen (2018) are briefly highlighted for the network in Fig. 2 with the global model (5) for the simple case that $\mathcal{H}$ and $\mathcal{D}$ are zero, $\mathcal{G} = I$ and the other system matrices having the following form:

$$\mathcal{A} = \begin{bmatrix} A_1 & A_{1,r} & & & \\ A_{2,\ell} & A_2 & \ddots & & \\ & \ddots & \ddots & \ddots & \\ & & & A_{N-1,r} & \\ & & & A_{N,\ell} & A_N \end{bmatrix} \quad (13)$$

$$\mathcal{B} = \text{Diag}(B_1, B_2, \dots, B_N),$$

$$\mathcal{C} = \text{Diag}(C_1, C_2, \dots, C_N)$$

The subspace identification methods focus on the identification of the i -th local system with model:

$$x_i(k+1) = A_i x_i(k) + [A_{i,\ell} \ A_{i,r}] \begin{bmatrix} x_{i-1}(k) \\ x_{i+1}(k) \end{bmatrix} \\ + B_i u_i(k) \quad y_i(k) = C_i x_i(k) + v_i(k) \quad (14)$$

These matrices characterize a spatially varying network. The missing information in addition to the local state vector $x_i(k)$ are the state vectors $x_{i-1}(k)$ and $x_{i+1}(k)$ of the neighboring nodes. This turns the identification problem into the class of *blind identification problems*. These are challenging problems for which no generic solution exists, and in general special structure of the problem needs to be exploited. To create such special structure, the following approach is taken in (Yu and Verhaegen 2018):

1. The system is partially lifted by collecting the local systems in the dashed boxes in Fig. 2

only for small values of R . For example, for the systems in the nodes $i+1 : i+R$, this results into the following state space model:

$$x_{i+1:i+R}(k+1) = A_{i+1:i+R} x_{i+1:i+R}(k) \\ + B_{i+1:i+R}^{\text{ext}} s_{i+1:i+R}(k) \\ + B_{i+1:i+R} u_{i+1:i+R}(k) \\ y_{i+1:i+R} = C_{i+1:i+R} x_{i+1:i+R}(k) \\ + v_{i+1:i+R}(k) \quad (15)$$

where the notation $\bullet_{i+1:i+R}(k)$ represents the stacking of all vectors or matrices $\bullet$ from nodes $i+1 : i+R$. Apart from the straightforwardly derived structure of the matrices $A_{i+1:i+R}$, $B_{i+1:i+R}$, and $C_{i+1:i+R}$, the matrix $B_{i+1:i+R}^{\text{ext}}$ has the following particular structure:

$$B_{i+1:i+R}^{\text{ext}} = \begin{bmatrix} A_{i+1,\ell} & 0 \\ 0 & 0 \\ \vdots & \vdots \\ 0 & 0 \\ 0 & A_{i+R,r} \end{bmatrix} \quad (16)$$

For these partially lifted state space model, the data equation that relates the block Hankel matrices of input and output data in subspace identification (Verhaegen 2015) is then subsequently constructed.

2. The structure of zeros in the matrix $B_{i+1:i+R}^{\text{ext}}$ in (16) and that in the similar matrix $B_{i-R+2:i+1}^{\text{ext}}$ is then exploited to find the state sequence $x_{i+1}(k)$ as the intersection between block Hankel matrices constructed from measured input and output data that appear in the data equations constructed in the previous step (Yu and Verhaegen 2018). In the same way, the state sequence $x_{i-1}(k)$ can be reconstructed. These intersection problems reveal the size of the state vectors $x_{i+1}(k)$ and $x_{i-1}(k)$ (which may be different).
3. The knowledge of the state sequences $x_{i+1}(k)$ and $x_{i-1}(k)$ allow to use classical subspace identification methods (Verhaegen 2015) to estimate (without parametrization) the

unknown system matrices and the size of the state vector $x_i(k)$ in (14).

Similar approaches by partial lifting have been derived for the identification of α -decomposable systems in Yu and Verhaegen (2018).

Subspace-Like Identification for Dense, Data Sparse Network Models

The identification of dense, data sparse network models turns out to be much harder than the sparse models considered in section “[Subspace Identification for Sparse Network Models](#).”

For the SSS systems, the methodology in Yu and Verhaegen (2018) does not apply as the partially lifted set of systems in the first step of the algorithm does no longer give rise to a sparse input weighting matrix of the unknown inputs of that lifted model like in (16). The derivation of a subspace algorithm for these class of systems is still ongoing research.

For the simple multilinear state space model in (10), a subspace-like identification methodology has recently been proposed. This method enables to derive information about key structural parameters like the size of the matrices A_1 and A_2 from data like in subspace methods; the numerical steps involve non-convex optimization problem, though of small size, and hence the name “subspace-like.”

For system identification, but also for control, these multidimensional systems postulate basic questions. An example is the “ambiguity” in terms of scaling and multiplication with invertible matrices of the system matrices that preserve the input-output behavior. For MSSM system such questions are dealt with in Siquin and Verhaegen (2019).

The solution in Siquin and Verhaegen (2019) considers the identification of the system matrices A_i, B_i, C_i in (10) up to “ambiguity” transformations. The method starts with the estimation of the (Markov) parameters $M_{i,r}$ and $M_{i,\ell}$ by approximating the input-output relationship under the assumption that (10) is stable:

$$Y(k) = \sum_{i=1}^{\infty} M_{i,r} U(k-i) M_{i,\ell}^T + V(k)$$

with an FIR model. Using alternating convex optimization, conditions for global convergence have been derived to find scaled variants of the parameters $M_{i,r}, M_{i,\ell}$ in the following way (Siquin and Verhaegen 2019):

$$\hat{M}_{i,r} \approx t_i M_{i,r} \quad \hat{M}_{i,\ell} \approx v_i M_{i,\ell} \quad \text{where } t_i v_i \approx 1$$

The approximation becomes an equality in the limit of increasing the order of the FIR model.

A bilinear optimization problem is then proposed in Siquin and Verhaegen (2019) to rescale these FIR parameters $\hat{M}_{i,r}, \hat{M}_{i,\ell}$ such that when stored into Hankel matrix, the latter gets (small) finite rank that should correspond to the orders of the system matrices A_1 and A_2 , respectively. These rescaled FIR parameters are then used in a 3D tensor framework (Siquin and Verhaegen 2019) to calculate the state sequence and the system matrices via SVDs. The latter provides structural information on the sizes of the system matrices in the model (10).

Summary and Future Directions

Two approaches are currently under full development for the identification of large-scale network-connected systems. Both have their merits and pitfalls. The selection of the most appropriate approach depends on what the model is used for. In this way the structured state space approach may be useful in the efficient design of controllers for network-connected systems as demonstrated in, e.g., in Rice and Verhaegen (2009) and Massioni and Verhaegen (2009). This is also the case for the identification methods presented in Siquin and Verhaegen (2019). The subspace-like methods presented in this overview may therefore open the avenue for *identification methods for distributed control of large-scale network-connected systems*.

This research field is rapidly expanding, and there are many possibilities for further research. Just a few examples are the development of new (subspace-like) algorithms for the open problems defined in this overview like for multilinear dynamical systems (MLDS). One interest-

ing development looming on the horizon is the parametrization and identification of network-connected systems in the context of tensor calculus (Sinquin and Verhaegen 2019; Bousse et al. 2017). Finally, the approaches outlined in this overview are able to identify large-scale state space models. A challenge remains to derive the network topology from these system matrices.

Image-Based Estimation for Robotics and Autonomous Systems

A. P. Dani

Electrical and Computer Engineering, University of Connecticut, Storrs, CT, USA

Abstract

This entry discusses methods to estimate the structure of the objects/scene observed using a series of moving camera images. To recover the structure, it is sufficient to estimate the depth of the feature points on the object. To this end, two observer-based depth estimation methods are presented. The first method is a concurrent learning-based observer for estimating the depth of the static feature points and the second method is an unknown input observer for estimating the depth of the moving feature points.

Keywords

Structure from motion · Range estimation · Nonlinear observers · Machine learning

Introduction

Recovering the structure of a static scene (i.e., the 3D Euclidean coordinates of feature points), using a moving camera is termed as ‘structure from motion (SfM)’. A number of solutions to the SfM problem are given in the form of batch or offline methods (Hartley and Zisserman 2003; Chaumette and Hutchinson 2006; Fathian et al. 2018) and causal or online methods (Jankovic

and Ghosh 1995; Dixon et al. 2003; Dani et al. 2012a). The solutions in computer vision applications mostly rely on offline processing of the data from a collection of images of the scene observed from different viewpoints. New advances in deep learning provide deep convolution neural network (CNN)-based solutions for estimating depth of every pixel in the image, but these methods require lot of training data to train the CNNs and do not utilize any geometric relationship information inherent to the problem. When the camera sensor is used in the context of navigation or visual feedback control, real-time estimation of the feature depth is required using online methods. The causal or online methods rely on image-based depth estimation using series of images obtained from a single moving camera and camera motion information. Feature depth estimation is one of the important topics in vision-based navigation and visual feedback control design for robotics and autonomous systems. The fundamental problem behind feature depth estimation is a triangulation problem. Since the object is assumed to be stationary, a moving camera can capture snapshots of the object from two different locations, and triangulation is feasible. When the camera and object both are moving, then the triangulation is not feasible from two views, which brings additional challenges to the design of online methods to recover the depth of feature points.

Many advances have been made in the field of online feature depth estimation of feature on static objects using extended Kalman filtering (Matthies et al. 1989) and nonlinear observer schemes (Jankovic and Ghosh 1995; Dixon et al. 2003; Hu et al. 2008; Dani et al. 2012b). The main idea of using observers is to utilize the most recent camera motion (linear and angular velocities and/or accelerations) and feature points data from the current image along with past depth estimates to update the current depth estimate. For the feature depth observers to converge, observability condition based on persistency of excitation (PE) must be satisfied. The PE condition provides conditions on camera motions that are least and most informative for the inverse depth estimation. In many practical application

scenarios, the image motion is very close to the least informative motion from the camera images. Examples of such scenarios include vertical landing of quadcopter/flying cars using downward-looking camera feedback, an approach motion along optical axis of camera for picking an object or a fruit by a robot manipulator using camera in-hand feedback. Monocular image feedback does not provide reliable feature depth information in these cases. Various other methods can be used to avoid this problem, such as a stereo camera pair or design of active perception, planning, and active control methods (Spica et al. 2017) that generate more informative camera motion for estimation of the feature depth. The use of stereo camera may not always be a feasible option due to its form factor and requires precise calibration and recalibration. Active structure from motion methods may not always find a solution to the path planning problem and may run into the issue of losing the features from the field of view (FOV). Also, in practical scenarios, the motion generated by most informative paths for depth estimation may not be desirable for successful completion of the control task. In addition, if the object is also moving, then the standard observers for depth estimation do not work since additional terms related to unknown motion of the moving object appear in the dynamics along with its depth parameter. Some offline solutions exist to solve this problem (Avidan and Shashua 2000), but they are not very useful for real-time feedback control.

In contrast, this chapter examines recent and emerging efforts that provide solutions to two important problems – (i) relaxation of restricted motion conditions present in depth estimation problem for static scene and (ii) the estimation of depth in dynamic scene. For the *first* problem, a concurrent learning (CL) method from adaptive control is used to design depth observers that reliably estimate the depth of the feature points when the camera motion paths are not very informative. The CL-based observers use data stored from the previous camera motion and depth estimates in the online depth estimation scheme. For the *second* problem, advances in the field of unknown input observer (UIO)

provide online solutions to the depth estimation in dynamics scenes where the unknown motion of the object is modeled as an unknown input. In the domain of online methods for depth estimation, the solutions to the aforementioned two problems provide significant advances for the utility of these algorithms in practical scenarios commonly observed in robotics and autonomous systems applications.

Image-Based Inverse Depth Dynamics

The movement of a perspective camera observing a scene results in the change of location of a feature point belonging to a static object in the image plane. Let $\bar{m}(t) = [X, Y, Z]^T \in \mathbb{R}^3$ and $m_n(t) = [\frac{X}{Z}, \frac{Y}{Z}, 1]^T \in \mathbb{R}^3$ be the Euclidean and normalized Euclidean coordinates of a feature point belonging to a static or moving object captured by a moving camera in the camera reference frame $\mathcal{F}_C$ with known camera velocities in the world reference frame $\mathcal{F}^*$. The normalized Euclidean coordinates can be converted to pixel coordinates $p = Am_n$ where $A \in \mathbb{R}^{3 \times 3}$ is the known camera calibration matrix. To estimate the depth, define an auxiliary vector $y(t) \in \mathbb{R}^3$, given by $x(t) = [\frac{X}{Z}, \frac{Y}{Z}, \frac{1}{Z}]^T$. Let $s(t) \in \mathbb{R}^2$ be an image plane feature point with first two components of $x(t)$ and $\chi \in \mathbb{R}$ be the inverse depth associated with the feature point. For a single feature point, define the state as $s = [x_1(t), x_2(t)]^T$ and the inverse depth as $\chi = x_3(t)$. Taking the time derivative of s , the dynamics of s as a function of linear and angular velocities of the camera can be expressed as

$$\dot{s} = f_m(s, \omega_c) + \Omega(s, v_c)\chi + d_s(s, v_p, \chi) \quad (1)$$

where $f_m(s, \omega_c) \in \mathbb{R}^2$ and $\Omega(s, v_c) \in \mathbb{R}^2$ are functions of measurable quantities or known quantities, $d_s(s, v_p, \chi) \in \mathbb{R}^2$ is a function of unmeasurable quantities, $v_c = [v_{cX}, v_{cY}, v_{cZ}]^T \in \mathbb{R}^3$ is the measurable linear velocity, $\omega_c = [\omega_{cX}, \omega_{cY}, \omega_{cZ}]^T \in \mathbb{R}^3$ is the measurable angular velocity of the camera, and $v_p = [v_{pX}, v_{pY}, v_{pZ}]^T \in \mathbb{R}^3$ is the linear

velocity of the moving point object. The dynamics associated with the inverse depth χ can be modeled as

$$\dot{\chi} = f_u(s, \chi, u) + d_\chi(\chi, v_p) \quad (2)$$

where $d_\chi(v_p, \chi) \in \mathbb{R}$ is a function of unmeasurable quantities. The state derivative $\dot{s} \in \mathbb{R}^2$ is not measurable and can only be estimated. If the object is stationary, then the terms $d_s(s, v_p, \chi)$ and $d_\chi(\chi, v_p)$ become zero and, hence, disappear from (1) and (2).

Problem Definition Given the measurements of feature points, $s(t)$ in successive frames and camera velocities $v_c(t)$ and $\omega_c(t)$ estimate the inverse depth $\frac{1}{\chi(t)}$ and, hence, 3D coordinate of the feature point, $\hat{m}(t)$. *Problem 1* – Perform the estimation when the object in the scene is stationary. *Problem 2* – Perform the estimation when the object in the scene is moving with non-zero unmeasurable velocity.

Depth Observers

Concurrent Learning-Based Depth Observer for Static Objects

CL (Chowdhary et al. 2013; Kamalapurkar et al. 2017) is a recently developed technique in adaptive control for parameter estimation, where the knowledge of recorded state information data, also known as the history stack of the system, is leveraged to estimate the parameters and achieve state tracking. CL methods can be used to guarantee parameter convergence in adaptive control without relying on the PE condition. Learning from recorded data is effective since it is based on the model error, which is closely related to the parameter estimation error. The use of history of system state information relaxes the PE condition to a finite excitation condition, which depends upon the rank of the regressor matrix (Chowdhary and Johnson 2010). Such a condition can be easily monitored online in comparison to the PE condition.

In the depth estimation dynamics (1)–(2), the inverse depth appears as a time-varying parameter in (1) with associated known dynamics. The convergence of depth estimation observers designed for the system in (1)–(2) relies on the satisfaction of the PE condition. For example, results in Chen and Kano (2004) and Dixon et al. (2003) provide discontinuous and continuous observer structure for depth estimation, respectively, under the assumption of known camera motion. Observer structures Dani et al. (2012a, b) provide a reduced order globally exponentially stable observer under fully known camera motion and partially unknown camera motion, respectively. All these depth observers require PE condition to be satisfied for their convergence results. Although many camera motions in practice satisfy the PE condition, in certain practical scenarios, motions that occur naturally during vision-based control tasks do not satisfy the PE condition. Then, the fundamental question is whether the concept of CL can be used to build a memory in the depth observer structure to relax the PE condition for estimating the depth in (1)–(2). Results in Rotithor et al. (2019) illustrate that such modifications to the depth observers are possible and provide full order observer structure to the problem. Since the depth is a time-varying parameter in the PDS, the exact estimation of the depth (asymptotic convergence of the observer error) in the absence of PE condition using CL-based observers is not possible. But the stability analysis of the observer structure with history stack information reveals that the recent history of the measurable part of the system state, state estimates, and camera motion contains information about the current inverse depth $\chi(t)$ and can be used to estimate the depth within a uniform ultimate bound even when the camera motion does not satisfy the PE condition.

Unknown Input Observer for Moving Objects

The problem of estimating the feature point depth in the presence of object motion adds another level of complexity to the estimation problem. In the system dynamics, additional unmeasurable

moving object's velocities appear that are multiplied by the unknown depth parameter. From the geometric perspective, batch solutions are provided in Avidan and Shashua (2000) for special object motions, such as straight lines or conic trajectories given five or nine views, respectively, and for more general curves in Kaminiski and Teicher (2004). Batch algorithms use an algebraic relationship between 3D coordinates of points in the camera coordinate frame and corresponding 2D projections on the image frame collected over n images to estimate the depth and structure. For visual servo control or video-based surveillance tasks, online structure estimation algorithms are required. Results in Dani et al. (2011) show that causal algorithms can be developed for estimating the structure of a moving object using a moving camera in the unknown input observer (UIO) framework. Conditions on object motion are developed when the estimation is exact in the sense of asymptotic convergence of the observer error. The object is assumed to be moving on a ground plane with arbitrary velocities observed by a downward-looking camera with arbitrary linear motion in 3D space. The advantage of causal methods of depth estimation is that no assumptions are required on the minimum number of points or minimum number of views necessary to estimate the structure in the design of the observer structure. In addition, online depth estimation methods are readily amenable to their incorporation in the feedback control loop structure.

Summary and Future Directions

Many online methods are available to estimate the depth of the feature points from the monocular camera feedback. These methods utilize the recursive estimation methods that use the structure of the nonlinearity of system and are robust to the external disturbances and sensor noise. An alternative to the aforementioned nonlinear observer schemes is to utilize observer theory from positive systems since feature depth

is always positive. Another alternative is to scale up the observer structure to include multiple feature points and include geometric constraints of the scene learned using machine learning methods, i.e., learn the physical relationship between the feature points in the observer structure. This confluence of machine learning and observer theory has a good potential of providing solutions to practical problems. Also, these methods can be extended to cases where the intermittent image or camera motion feedback is available to the observer scheme (cf. Parikh et al. 2018).

The utility of the online observers for depth or relative depth estimation for long-term simultaneous localization and mapping (SLAM) and long-term navigation of the autonomous systems using image-based feedback needs to be tested. Specifically, studying the CL-based observers in the context of utilizing memory in the estimation scheme by storing and observing similar patterns occurred in the past can lead to more reliable estimation scheme for long-term autonomy and navigation. With the continued development of the CL-based and other learning schemes in observer design, more long-term estimation schemes are likely to emerge. With the advancements of deep learning, image-based estimation for imitation learning or learning from demonstration (Ravichandar and Dani 2019) in robotics and autonomous systems will also be a potential direction of growth.

Image-Based Formation Control of Mobile Robots

Guoqiang Hu, Zhi Feng, and Renhe Guan
School of Electrical and Electronic Engineering,
Nanyang Technological University, Singapore,
Singapore

Abstract

This chapter addresses an image-based cooperative formation control problem of multiple mobile robots. To develop the image-based feedback controller, the homography matrix or essential matrix techniques are employed to achieve geometric relationships that are beneficial to image-based formation control. Then, image-based cooperative state estimation and cooperative formation control designs are considered, respectively. Finally, a short discussion section is provided to summarize existing research and to point out several future research directions.

Keywords

Image-based formation · Cooperative state estimation · Cooperative control

Introduction

Robot formation control (e.g., see Egerstedt and Hu (2001), Balch and Arkin (1998), Das et al. (2002), Paley and Leonard (2007), Sun et al. (2009), and Ren (2010), just name a few) is an interesting topic and has a wide range of applications in robotics and transportation. This chapter will focus on cooperative state estimation and cooperative formation control, two important problems under this topic.

The cooperative state estimation problem is motivated by a vision-based formation control problem based on relative measurements (Cook and Hu 2012). One of the convenient ways to make relative measurements within a formation of robots is to use cameras mounted to the robots.

Because of the field of view constraints, occlusions, and resolution that limit the cameras' measurement capabilities, it is unlikely that each robot will be able to make all the measurements necessary to completely describe the formation. That is, each robot can only measure part of the relative state information, while the rest of the information is measured by other robots. In order for the robots to have a precise estimate of the state in a distributed manner, there needs to be a method for combining and distributing the information measured by different robots.

Cooperative formation control of multi-robot systems has caught a growing interest in both the robotics and control communities. The objective of this problem is to enable a team of robots to maintain a certain formation configuration while performing a group motion. Several methods are proposed to address this problem (e.g., virtual structure method (Egerstedt and Hu 2001), behavior-based method (Balch and Arkin 1998), leader-following method (Das et al. 2002), potential function method (Paley and Leonard 2007), synchronous formation method (Sun et al. 2009), and consensus method (Ren 2010)). The position and orientation of each robot in a global reference frame are often required for cooperative formation control of the robotic network. However, it is desirable to remove the dependence on a global reference frame due to sensing and communication limits in practical systems. The removal of global reference frame leads toward describing the state of the formation in terms of the relative positions and orientations of the robots or in terms of the geometry of the formation. Cameras and computer vision algorithms are capable of making relative measurements.

Geometric Relationships

This section focuses on the geometric relationships that are beneficial to image-based formation control. To develop control laws, it is assumed that images can be obtained, analyzed, and transmitted to the controller without restricting the control rates. One type of data source used in

image-based feedback control is feature point which can be identified and tracked among images. With these feature points, the rotation and scaled translation of camera can be estimated, based on homography matrix or essential matrix techniques. In the following, the homography matrix for four coplanar points and essential matrix for eight non-coplanar feature points are introduced briefly.

Homography Matrix

Suppose that there are four coplanar but non-collinear feature points in a plane π as illustrated in Fig. 1. It is reasonable to suppose that feature points lie on a plane, which does not reduce the generality of the results. If there does not exist four available target feature points, then methods like virtual parallax algorithm can be exploited to create virtual planes from non-planar feature points.

In Fig. 1, $\mathcal{F}$ represents the coordinate frame which is affixed to the current camera pose, while the stationary coordinate frame $\mathcal{F}^*$ is affixed to the constant expected camera position and orientation. The Euclidean coordinates of feature points O_i are given by $\bar{m}_i(t) \in \mathbb{R}^3$ and $\bar{m}_i^*(t) \in \mathbb{R}^3$ in frames $\mathcal{F}$ and $\mathcal{F}^*$, respectively

Image-Based Formation Control of Mobile Robots, Fig. 1 Geometric relationships between coordinate frames

$$\begin{aligned}\bar{m}_i &= [x_i(t) \quad y_i(t) \quad z_i(t)]^T \\ \bar{m}_i^* &= [x_i^* \quad y_i^* \quad z_i^*]^T\end{aligned}\quad (1)$$

where $x_i(t)$, $y_i(t)$, and $z_i(t) \in \mathbb{R}$ stand for the Euclidean coordinates of the i th feature point and x_i^* , y_i^* , and $z_i^* \in \mathbb{R}$ are Euclidean coordinates of the corresponding feature points $\mathcal{F}^*$. From the direct geometry relationship, it can be found that

$$\bar{m}_i = x_f + R\bar{m}_i^* \quad (2)$$

where $R(t) \in SO(3)$ is a rotation matrix to describe the orientation of frame $\mathcal{F}^*$ with respect to $\mathcal{F}$. $x_f \in \mathbb{R}$ represents the translation from these two frames, and it is expressed in the frame $\mathcal{F}$. Then, $\bar{m}_i$ and $\bar{m}_i^*$ can be normalized as

$$m_i = [m_{xi} \quad m_{yi} \quad 1]^T = \begin{bmatrix} \frac{x_i}{z_i} & \frac{y_i}{z_i} & 1 \end{bmatrix}^T \quad (3)$$

$$m_i^* = [m_{xi}^* \quad m_{yi}^* \quad 1]^T = \begin{bmatrix} \frac{x_i^*}{z_i^*} & \frac{y_i^*}{z_i^*} & 1 \end{bmatrix}^T \quad (4)$$

Then, plugging Equations (3) and (4) into Equation (2), the following relationship between $m_i(t)$ and m_i^* can be attained as

$$m_i = \frac{z_i^*}{z_i} \left(R + \frac{x_f}{d^*} n^{*T} \right) m_i^* \quad (5)$$

where $\alpha_i(t) \in \mathbb{R}$ can be denoted as $\alpha_i(t) = \frac{z_i^*}{z_i}$ and Euclidean homography matrix $H(t) \in \mathbb{R}^{3 \times 3}$ is $H(t) = R + \frac{x_f}{d^*} n^{*T}$. The matrix $H(t)$ includes the translation vector $x_f(t)$, the distance $d^* \in \mathbb{R}$ from the origin of $\mathcal{F}^*$ to the plane π , the rotation matrix R , and $n^* \in \mathbb{R}^3$ representing the unit normal vector to the plane π . In the image coordinate frame, each feature point O_i has the pixel coordinate $p_i(t) \in \mathbb{R}^3$, $p_i^* \in \mathbb{R}^3$ expressed in the current and expected image as

$$p_i = [u_i \quad v_i \quad 1]^T \quad p_i^* = [u_i^* \quad v_i^* \quad 1]^T \quad (6)$$

and $u_i(t)$, $v_i(t)$, u_i^* , and v_i^* belong to $\mathbb{R}$. According to the pinhole camera model,

$$p_i = A m_i \quad p_i^* = A m_i^* \quad (7)$$

$$A = \begin{bmatrix} \alpha & -\alpha \cot \varphi & u_0 \\ 0 & \frac{\beta}{\sin \varphi} & v_0 \\ 0 & 0 & 1 \end{bmatrix} \quad (8)$$

where $A \in \mathbb{R}^{3 \times 3}$ is the constant camera calibration matrix, and $u_0, v_0 \in \mathbb{R}$ are the pixel coordinates of image center. $\alpha, \beta \in \mathbb{R}$ stand for the product of camera scaling factors and the focal length, and $\varphi \in \mathbb{R}$ is the skew angle between the camera axes. Usually, this angle is small and can be neglected in some occasions. Further, (5) can be expressed with p_i^* as

$$p_i = \alpha_i (A H A^{-1}) p_i^* \quad (9)$$

The projective homography of the camera can be described by (9). With the four feature points, the Euclidean homography matrix H can be solved, and the relative pose between two frames is also able to be obtained with H .

Essential Matrix

Assume that there are at least eight points and they have been already matched by some image processing methods. It is not necessary for these

eight matched feature points to be coplanar. Instead, no four feature points are coplanar in this case. With such eight feature points, another camera pose estimation method based on the essential matrix can be derived as follows.

Similarly, a pair of matched feature points m_j^* and m_j from two frames $\mathcal{F}$ and $\mathcal{F}^*$ can be represented as

$$m_j(t) = \begin{bmatrix} x_j(t) & y_j(t) & 1 \\ z_j(t) & z_j(t) & 1 \end{bmatrix}^T$$

$$m_j^* = \begin{bmatrix} x_j^* & y_j^* & 1 \\ z_j^* & z_j^* & 1 \end{bmatrix}^T \quad (10)$$

Also, the coordinates of each point in the images are related by

$$z_j m_j = z_j^* R m_j^* + x_f \quad (11)$$

Let the following $[x]_{\times}$ define a skew-symmetric matrix so that $[x]_{\times} m = x \times m$, where $\times$ here denotes the cross product between two vectors.

$$[x]_{\times} = \begin{bmatrix} 0 & -x_3 & x_2 \\ x_3 & 0 & -x_1 \\ -x_2 & x_1 & 0 \end{bmatrix} \quad (12)$$

where x_1, x_2 , and $x_3 \in \mathbb{R}$ are the elements of the vector $x = [x_1, x_2, x_3]^T$. Pre-multiply Equation (11) by $[x_f]_{\times}$, it can be found that

$$z_j [x_f]_{\times} m_j = z_j^* [x_f]_{\times} R m_j^* \quad (13)$$

Note that $z_j m_j^T [x_f]_{\times} m_j = 0$ and $z_j m_j (x_f \times m_j) = 0$. Thus,

$$z_j^* m_j^T [x_f]_{\times} R m_j^* = m_j^T E m_j^* = 0 \quad (14)$$

The matrix E here is the essential matrix and can be denoted as $E = [x_f]_{\times} R$. If these eight feature points or more points are available, the essential matrix E can be estimated using linear algebra methods. Then the transformation matrix between two camera frames is solved with the matrix E .

Graph Theory

In this section, we present some basic graph theory concepts following Diestel (2000) that are essential in the study of multi-robot systems.

Let $\mathcal{G} = \{\mathcal{V}, \mathcal{E}\}$ represent a graph and $\mathcal{V} \in \{1, \dots, N\}$ be the set of vertices. The set of edges is denoted as $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$. Assume that there is no self-loops in the graph, i.e., $(i, i) \notin \mathcal{E}$. $\mathcal{N}_i = \{j \in \mathcal{V} \mid (j, i) \in \mathcal{E}\}$ denotes the neighborhood set of vertex i . In a directed graph $\mathcal{G}$, $(i, j) \in \mathcal{E}$ denotes that the node j can obtain information from the node i , but not necessarily vice versa. $\mathcal{G}$ contains a directed spanning tree if there is a node that can reach other nodes via a directed path. $\mathcal{G}$ is undirected if for $(i, j) \in \mathcal{E}$, edge $(j, i) \in \mathcal{E}$. Let $\bar{\mathcal{G}} = (\bar{\mathcal{V}}, \bar{\mathcal{E}})$ represent a graph of a network with one leader and N followers, where $\bar{\mathcal{E}} \subseteq \bar{\mathcal{V}} \times \bar{\mathcal{V}}$, $\bar{\mathcal{V}} = \{0, 1, 2, \dots, N\}$, and 0 are associated with the leader. Then, the neighbor set of node i can be denoted as $\bar{\mathcal{N}}_i = \{j \neq i, (j, i) \in \bar{\mathcal{E}}\}$. $A = [a_{ij}] \in \mathbb{R}^{N \times N}$ denotes the adjacency matrix of $\mathcal{G}$, where $a_{ij} > 0$ if and only if $(j, i) \in \mathcal{E}$, else $a_{ij} = 0$. The in-degree and out-degree of node i are $d_i^I = \sum_{j=1}^N a_{ij}$ and $d_i^O = \sum_{j=1}^N a_{ji}$, respectively. Then, a graph is balanced if $d_i^I = d_i^O$ for all i . $L \triangleq D - A \in \mathbb{R}^{N \times N}$ is called the Laplacian matrix of $\mathcal{G}$, where $D = [d_{ij}] \in \mathbb{R}^{N \times N}$ is the in-degree matrix with $d_{ij} = 0$, $i \neq j$, and $d_{ii} = \sum_{j=1}^N a_{ij}$. The matrix L is symmetric for an undirected graph, while for a directed one, it is not necessarily symmetric. In a leader-following network, $H \triangleq L + B \in \mathbb{R}^{N \times N}$ represents the information-exchange matrix, where B is a diagonal matrix whose i th diagonal element is a_{i0} with $a_{i0} > 0$ if $(0, i) \in \bar{\mathcal{E}}$ and $a_{i0} = 0$, otherwise.

Consider several examples for undirected and directed graphs in Figs. 2, 3, and 4. The graph in Fig. 2 is connected and undirected, where the adjacency matrix and Laplacian matrix are symmetric. In contrast, the graph in Fig. 3 is directed with a spanning tree from each node, where the adjacency matrix and Laplacian matrix are not symmetric. Figure 4 depicts the directed graph with a spanning tree from the leader 0, where H is not symmetric.

Cooperative State Estimation

The cooperative state estimation is crucial in achieving robot formation control (Cook et al. 2012). Usually in multi-robot control process, all robots are only equipped with limited sensors like cameras, which can only detect and measure part of relative state information, while the rest of information is measured by other robots. It is mainly because these sensors have limited measurement ranges both in depth and angle, which makes it nearly impossible for robots to observe states of all other ones. In order for a robot to have a precise estimation of the states in the robot group, distributed cooperative state estimation methods are needed.

In recent years, there have been several methods proposed to solve this problem. In general, they can be categorized into Bayesian-based approaches, non-Bayesian-based approaches, and distributed Kalman filter-based approaches. In most Bayesian-based methods, e.g., in Kwon and Hwang (2019), the prior knowledge like robot model, initial states, and multi-robot topology structure is always integrated with the posterior information including measurements from sensors, transmitted data from other robots. With this information, Bayesian-based schemes can be employed in the multi-robot system to obtain more precise state estimation.

However, under certain conditions where prior knowledge is not available, non-Bayesian-based approaches will become effective and suitable. For example, sometimes, we may know little about the system dynamics of the robot, environment information, and network topology among multiple robots. In Nedic et al. (2017), a distributed non-Bayesian learning algorithm is proposed for multiple robots with complicated network structure, and it can ensure that all agents in the network agree on the hypothesis that best explains the measurement data. Also, a nonasymptotic, explicit, and geometric convergence rate is provided. In Mateos and Giannakis (2012), a distributed recursive least squares method is presented to solve the cooperative estimation problem for multiple robots with ad

Image-Based Formation Control of Mobile Robots, Fig. 2 Example of an undirected graph

Image-Based Formation Control of Mobile Robots, Fig. 3 Example of a directed graph

Image-Based Formation Control of Mobile Robots, Fig. 4 Example of a directed leader-following graph

hoc wireless sensors. The distributed iteration laws are attained by minimizing the exponentially weighted least squares cost with the alternating minimization algorithm.

In addition, there are works reported on cooperative estimation using distributed Kalman filter. In Carli et al. (2008), distributed Kalman filters are designed for consensus control problems. These presented filters can estimate the states of target robots and drive the states of all robots to achieve final consensus goal together. Also, in Tu and Sayed (2012), diffusion strategies are utilized for cooperative state estimation. It is shown that diffusion network has a faster convergence rate and can reach lower mean square deviation than consensus networks. The mean square stability of

diffusion network is not sensitive to the provided weights, either. As for Wang et al. (2017), the cases where the process model of interest is uncertain to all robots are discussed. With the proposed methods in these papers, all local robots can identify the underlying model and estimate the expected states.

Cooperative Formation Control

Over the past decades, vision-based cooperative formation control has attracted considerable attention due to the low cost and rich information that cameras can provide in comparison with other traditional sensors (e.g., laser range finders,

radar, sonars, etc.). In a multi-robot system, position and orientation measurements are typically required in cooperative formation control. One observation is that the global position system may not be available in certain environments, e.g., indoor and underwater situations. The error drift is usually inevitable when using inertial measurement units, which leads to inaccuracy or even failure in achieving robot formation. LIDAR sensors have also been widely utilized to provide navigation and localization, while they are expensive.

In contrast, rather than using the aforementioned sensors, cameras enabling a reach data set in a relatively cheap and versatile manner attract increasingly attention to recast the navigation and control problem in terms of the imaged-based vision feedback. Solving the cooperative formation control problem exclusively with onboard vision sensors is challenging, because cameras provide the view angles to the other robots but not the distances or positions/velocities as required in Egerstedt and Hu (2001), Balch and Arkin (1998), Das et al. (2002), Paley and Leonard (2007), Sun et al. (2009), and Ren (2010). The image-based visual feedback relies on the features that are extracted from images, and controllers are derived via image features.

There have been a few works on vision-based formation control in Das et al. (2002), Vidal et al. (2004), Moshtagh et al. (2009), and Mariottini et al. (2009). The omnidirectional cameras are utilized in Das et al. (2002) and Vidal et al. (2004) for multi-robot formation control via an input-output feedback linearization. In particular, a centralized control framework is proposed in Das et al. (2002) for vision-based leader-follower formation control. Both camera-intrinsic calibration parameters and vertical pose of the camera are supposed a priori known to compute both the bearing and distance. Vidal et al. (2004) further introduced a motion segmentation technique to achieve formation of nonholonomic mobile robots with calibrated vision sensors. To remove the distance measurement, the vision-based localization problem is introduced in Mariottini et al. (2009) where the leader adopts an extended Kalman filtering to localize its followers, and computes the control inputs and

guides the formation in a centralized fashion. A visual-based distributed control architecture is introduced in Moshtagh et al. (2009) where the proposed controllers are coordinate-free and rely on only measurements of bearing and optical flow rather than distance measurements or communication of heading information among neighbors.

Notice that the aforementioned results assume that the robots have omnidirectional (or pancontrolled) cameras and that the linear and angular velocities of leader are either communicated to or estimated by followers. However, when communication between robots is absent and/or their onboard camera sensors have limited capabilities (e.g., limited range and angle of view), then the robots can typically stay connected if and only if the leader is always visible to followers. Hence, the latter specification imposes a set of visibility constraint. A related work is Morbidi et al. (2011) that aims to enable groups of mobile robots to visually maintain formations in the absence of communication. Recently, formation control under visibility constraints is studied in Panagou and Kumar (2009) for multi-robots with unicycle kinematics in known obstacle environments via vision-based formation control.

Summary and Future Directions

In contrast to existing coordination works in multi-robot systems based on either position or distance measurements, the image-based cooperative estimation and formation control problems are considered. Since the onboard cameras usually have limited capabilities in practice, each robot can only measure part of the relative measurements within a formation of robots. A consensus-based method can be leveraged to synthesize the cooperative state estimation algorithm such that the measurements made by each individual robot are integrated to obtain a complete description of the formation. This method can be applied to vision-based cooperative formation control of multiple mobile robots in the absence of global reference frames.

Achieving distributed coordinated control of real-world, vision-based multi-robot systems is a

difficult problem because of the associated sensing and communication constraints, complexity, and uncertainties (e.g., field of view (FOV) constraint, camera frame rate limit, image noise, disturbances, unmodeled dynamics, propagation of errors, and dynamically changing topologies, etc.). It is an important issue due to its wide range of potential applications in surveillance and search, highway traffic monitoring, intelligent transportation, environment monitoring, and unmanned exploration of dangerous areas. Vision-based robot systems have enormous potential to become the best among man-made coordinated autonomous systems. At present, however, sensing, communication, and coordination complexities limit the applications.

The emerging research area of image-based cooperative estimation and control is far from being fully explored, and many problems still remain unsolved. One common feature in the existing works is that the underlying graph is time-invariant and undirected. This may not be valid in practical tasks as the onboard camera of each robot has limited sensing abilities and the vision may be blocked or lost in practical dynamical environments. As a result, the interaction network is modeled as dynamic and directed information-exchange topologies. In such a situation, the cooperative state estimation and cooperative control problems would become much more complicated.

Another future direction is time-varying formation tracking control of multi-robot systems. The existing cooperative formation control works assume that the scale and pattern of the formation is always fixed, while in real robot applications, e.g., source seeking or target enclosing, the formation of a team of robots may change as time evolves and is required to track a trajectory to perform tasks. In such scenarios, time-varying formation tracking problems arise where robots can not only keep the time-varying formation but also track the trajectory. New distributed tools are demanded to handle this case.

In addition to cooperative estimation and formation control, other practical tasks required to accomplish with visual-based measurements include imaged-based target tracking,

rendezvous, swarming, mapping, etc. To achieve the missions, additional requirements on the sensing, communication, and computation complexities have to be taken into account, especially in an unknown dynamic environment to avoid collisions among robots and obstacles.

Abstract

Humans are able to sense and respond to changes in the real world without an exact knowledge of sensory-to-motor transformation. By using visual feedback, we can pick up various new objects or tools and manipulate them easily to perform various visually guided tasks without an accurate knowledge of the kinematics and dynamics. This basic ability gives us a high degree of flexibility in dealing with unforeseen changes in the real world. Inspired by this natural phenomenon, much progress has been obtained in vision-based control of robots. This entry introduces the basic concepts in image-based robot control from a system control theory point of view.

Keywords

Image based control · Robot control · Adaptive control

Introduction

Vision-based control or visual servoing has been extensively used in many modern control applications such as visual-based grasping and assembly in factory automation, autonomous navigation and micro-manipulation. In vision-based control problems, the control inputs are generated based on visual feedback information obtained from a vision system which typically consists of cameras and image processing algorithms. In general, visual servoing methods can be classified into two main categories including position/pose-based visual servoing (PBVS) and image-based visual servoing (IBVS) (Hutchinson et al. 1996). For PBVS, the object of interest is the 3D position or pose parameters of the target, and the task requirements are defined in Cartesian space. In this approach, the exact camera models are required to determine the position or orientation information in Cartesian space based on the visual information obtained from the vision system in image space. In IBVS, the task requirements are directly defined in image space. Since the image error information is directly used to regulate the control input, IBVS methods are more robust to camera calibration errors. In robot visual servo control schemes, the cameras are either placed at fixed positions, which is named as eye-to-hand configuration or mounted on the robots, which is named as eye-in-hand configuration (Hutchinson et al. 1996).

In image-based control, the control objective can be expressed as a regulation or tracking problem of the visual feature error defined as $\Delta \mathbf{x} = \mathbf{x} - \mathbf{x}_d$, where $\Delta \mathbf{x}$ denotes the vector of visual feature error, $\mathbf{x}$ denotes the visual feature, and $\mathbf{x}_d$ denotes the desired visual feature or trajectory in image space. Since the errors are specified in image space and control inputs of the robots are issued at joint level or actuator level, a transformation matrix is needed to convert the error in

image space into input commands in joint space. In robotics, Jacobian matrix plays the role of transforming the image error to joint commands. Let $\dot{\mathbf{q}}$ denote the joint velocity in joint space and $\dot{\mathbf{x}}$ denote the velocity of the visual feature point in image coordinate; the relationship between $\dot{\mathbf{q}}$ and $\dot{\mathbf{x}}$ is defined as (Hutchinson et al. 1996):

$$\dot{\mathbf{x}} = \mathbf{J}_s \mathbf{J}_r \dot{\mathbf{q}} = \mathbf{J} \dot{\mathbf{q}} \quad (1)$$

where $\mathbf{J}$ denotes the overall Jacobian matrix from joint space to image space, $\mathbf{J}_r$ denotes the Jacobian matrix from joint space to Cartesian space, and $\mathbf{J}_s$ denotes the image Jacobian matrix from Cartesian space to image space.

The joint commands for image-based robot control can be designed in two ways depending on the architectures of the robot control systems. Most industrial robot systems have a closed architecture control system where the user inputs can only be specified as position or velocity commands. A joint-space controller or inner controller is used to control the robot, but the controller is fixed, and the torque or voltage control inputs to the motors are not accessible by the users. In this case, the image-based controller is added as an external feedback loop as illustrated in Fig. 1. For robot systems with an open-architecture control system, the inputs can be specified as input torques or voltage to the motors or actuators, and the image-based feedback controller can be designed directly.

Traditional visual servoing techniques are mostly defined as the reference joint velocity as illustrated in Fig. 1. A typical visual servo controller is given as (Hutchinson et al. 1996):

$$\dot{\mathbf{q}}_r = -k_p \mathbf{J}^+ \Delta \mathbf{x} \quad (2)$$

where $\dot{\mathbf{q}}_r$ denotes the reference velocity command in joint space and $\mathbf{J}^+$ denotes the pseudo-inverse of $\mathbf{J}$. The pseudo-inverse of the Jacobian matrix, $\mathbf{J}^+$, is used to transform the servo error from image space to joint space. The reference joint velocity command is then used as the reference inputs of the inner loop to control the robot, and thus the accuracy of the visual servoing also relies on the performance of the inner controller. Such controller is also commonly named as kinematic visual servo controller as the dynamics of the robots or the inner control loop are not taken into consideration in the design and analysis of the closed-loop control systems. The advantage of the kinematic visual servoing approach is that it can be easily implemented on most industrial robotic systems with closed control architecture. It can also be shown that the external loop is locally stable in presence of camera calibration errors.

Dynamic Image-Based Controller

One issue in the design of the kinematic visual servo controller is that the effects of robot dynamics or the interactions with the inner control loop are neglected, and therefore the stability of the overall system is not analyzed. For robots with open-architecture control system, the image-based controller can be designed directly as the torque or voltage inputs as shown in Fig. 2, taking into consideration the effects of the robot dynamics.

Image-Based Robot Control, Fig. 1 Vision based control with closed control architecture

Image-Based Robot Control, Fig. 2 Image based control with open control architecture

The dynamic model of a robot manipulator is given as (Arimoto 1996):

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \left[\frac{1}{2}\dot{\mathbf{M}}(\mathbf{q}) + \mathbf{S}(\mathbf{q}, \dot{\mathbf{q}}) \right] \dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) = \boldsymbol{\tau} \quad (3)$$

where $\mathbf{M}(\mathbf{q})$ is the manipulator inertia matrix which is symmetric and positive definite; $[\frac{1}{2}\dot{\mathbf{M}}(\mathbf{q}) + \mathbf{S}(\mathbf{q}, \dot{\mathbf{q}})]\dot{\mathbf{q}}$ denotes the centripetal and Coriolis torques, where $\mathbf{S}(\mathbf{q}, \dot{\mathbf{q}})$ is skew-symmetric; and $\mathbf{g}(\mathbf{q})$ represents the vector of gravitational torques, $\boldsymbol{\tau}$ stands for the vector of control input.

Approximate Jacobian Setpoint Control

A simplest form of dynamic image-based robot control is the proportional-derivative (PD) controller designed in torque control mode as follows: (Cheah et al. 2003):

$$\boldsymbol{\tau} = -\hat{\mathbf{J}}^T \mathbf{K}_p \text{sat}(\Delta \mathbf{x}) - \mathbf{K}_v \dot{\mathbf{q}} + \mathbf{g}(\mathbf{q}) \quad (4)$$

where $\hat{\mathbf{J}}$ denotes the approximate Jacobian matrix, $\text{sat}(\Delta \mathbf{x})$ denotes a saturated function, and $\mathbf{K}_v$ and $\mathbf{K}_p$ denote the constant gain matrices which are positive definite. The basic idea is to form a saturated virtual spring force $\mathbf{K}_p \text{sat}(\Delta \mathbf{x})$ in image space and convert it to torque in joint space by using the transpose Jacobian matrix. The role of the saturated function is to bound the visual feedback error $\Delta \mathbf{x}$ when it is large. The basic idea stems from visually guided reaching tasks of human where only the directional information is used when the position error is large. That is, the magnitude is not important at the beginning stage and thus can be saturated, and hence only the directional information is used. The magnitude of the position error is only

monitored when the target is nearer. The second term in (4) is a joint-spring damping term, and the last term is used to compensate gravitational torques. The stability of the closed-loop robot control system shown by (3) and (4) can be guaranteed by using Lyapunov method, and the details can be found in Cheah et al. (2003).

Adaptive Jacobian Control

The PD controller with gravity compensator in (4) is used for setpoint task, and the estimated parameters of the approximate Jacobian matrix are not updated upon to improve the performance. For tracking control problem in presence of uncertain parameters, adaptive control approach (Slotine and Li 1987) is widely adopted, in which the estimated parameters are adjusted online by using the feedback error. The key challenges in developing image-based adaptive robot control (Cheah et al. 2006) are that the kinematic parameters are not linearly parameterized in task-space dynamics and hence cannot be updated together with the dynamic parameters. The depth, kinematic, and dynamic parameters have to be updated separately to preserve stability.

Let $\mathbf{J}_s = \mathbf{Z}^{-1}\mathbf{L}$ in (1) where $\mathbf{Z}$ denoted as a diagonal matrix that contains the depth information of the feature points with respect to the camera image frame and $\mathbf{L}$ a Jacobian matrix. Note that both $\mathbf{Z}\dot{\mathbf{x}}$ and $\mathbf{J}_m\dot{\mathbf{q}}$ where $\mathbf{J}_m = \mathbf{L}\mathbf{J}_r$ are linear in sets of kinematic and camera parameters such that $\mathbf{J}_m\dot{\mathbf{q}} = \mathbf{Y}_k(\mathbf{q}, \dot{\mathbf{q}})\boldsymbol{\theta}_k$ and $\mathbf{Z}\dot{\mathbf{x}} = \mathbf{Y}_z(\mathbf{q}, \dot{\mathbf{x}})\boldsymbol{\theta}_z$ where $\mathbf{Y}_k(\mathbf{q}, \dot{\mathbf{q}})$ and $\mathbf{Y}_z(\mathbf{q}, \dot{\mathbf{x}})$ denote the kinematic regressor matrix and depth regressor matrix, respectively, and $\boldsymbol{\theta}_k$ and $\boldsymbol{\theta}_z$ denote the unknown constant kinematic parameter vector and the unknown constant depth parameter vector, respectively.

An adaptive Jacobian image-based controller is given as:

$$\begin{aligned} \tau = & -\hat{\mathbf{J}}_m^T(\hat{\boldsymbol{\theta}}_k)\hat{\mathbf{Z}}^{-1}(\hat{\boldsymbol{\theta}}_z)(\mathbf{K}_v\Delta\dot{\mathbf{x}} + \mathbf{K}_p\Delta\mathbf{x}) \\ & + \mathbf{Y}_d(\mathbf{q}, \dot{\mathbf{q}}, \dot{\mathbf{q}}_r, \ddot{\mathbf{q}}_r)\hat{\boldsymbol{\theta}}_d \end{aligned} \quad (5)$$

where

$$\dot{\mathbf{q}}_r = \hat{\mathbf{J}}_m^+(\hat{\boldsymbol{\theta}}_k)\hat{\mathbf{Z}}(\hat{\boldsymbol{\theta}}_z)[\dot{\mathbf{x}}_d - \alpha(\mathbf{x} - \mathbf{x}_d)] \quad (6)$$

with $\Delta\dot{\mathbf{x}} = \dot{\mathbf{x}} - \dot{\mathbf{x}}_d$ and $\dot{\mathbf{x}} = \hat{\mathbf{Z}}^{-1}\hat{\mathbf{J}}_m\dot{\mathbf{q}}$ with $\hat{\mathbf{Z}}$ and $\hat{\mathbf{J}}_m$ denoted as the approximate matrices of $\mathbf{Z}$ and $\mathbf{J}_m$, respectively, and $\mathbf{Y}_d(\mathbf{q}, \dot{\mathbf{q}}, \dot{\mathbf{q}}_r, \ddot{\mathbf{q}}_r)$ denotes the dynamic regressor matrix. The update laws to estimate the unknown dynamic, kinematic, and depth parameters, respectively, are:

$$\dot{\hat{\boldsymbol{\theta}}}_d = -\mathbf{L}_d\mathbf{Y}_d(\mathbf{q}, \dot{\mathbf{q}}, \dot{\mathbf{q}}_r, \ddot{\mathbf{q}}_r)(\dot{\mathbf{q}} - \dot{\mathbf{q}}_r) \quad (7)$$

$$\dot{\hat{\boldsymbol{\theta}}}_k = \mathbf{L}_k\mathbf{Y}_k^T(\mathbf{q}, \dot{\mathbf{q}})\hat{\mathbf{Z}}^{-1}(\mathbf{K}_v\Delta\dot{\mathbf{x}} + \mathbf{K}_p\Delta\mathbf{x}) \quad (8)$$

$$\dot{\hat{\boldsymbol{\theta}}}_z = -\mathbf{L}_z\mathbf{Y}_z^T(\mathbf{q}, \dot{\mathbf{x}})\hat{\mathbf{Z}}^{-1}(\mathbf{K}_v\Delta\dot{\mathbf{x}} + \mathbf{K}_p\Delta\mathbf{x}), \quad (9)$$

where $\mathbf{L}_d$, $\mathbf{L}_k$, and $\mathbf{L}_z$ are gain matrices that are symmetric and positive definite. The detailed stability analysis can be found in Cheah and Li (2015).

Separation of Kinematic and Dynamic Control Loops

In kinematic visual servoing, the controller is implemented as an outer feedback control loop as illustrated in Fig. 1, and the stability of the overall system is not analyzed since the external control loop and inner control loop are treated as independent systems. In dynamic visual servoing, the stability of the system can be analyzed directly, but it is not applicable for robots with closed control architecture. One way to overcome these problems is the use of a design approach (Wang 2016), which realizes the separate designs of the kinematic and dynamic control loops while preserving the stability of the overall system when integrating them together.

For the kinematic control loop, the controller is specified as the joint velocity command that can be directly fed into the inner joint servo loop as:

$$\dot{\mathbf{q}}_r = \hat{\mathbf{J}}^+(\hat{\boldsymbol{\theta}}_k)\dot{\mathbf{x}}_d - \hat{\mathbf{J}}^T(\hat{\boldsymbol{\theta}}_k)\alpha\Delta\mathbf{x} \quad (10)$$

where the estimated kinematic parameters are updated as:

$$\dot{\hat{\boldsymbol{\theta}}}_k = \mathbf{L}_k\mathbf{Y}_k^T(\mathbf{q}, \dot{\mathbf{q}})\Delta\mathbf{x}. \quad (11)$$

Let the velocity tracking error for the inner joint servo control loop be defined as $\mathbf{s} = \dot{\mathbf{q}} - \dot{\mathbf{q}}_r$, if the inner control loop is designed so that the joint velocity error $\mathbf{s} \in L_2 \cap L_\infty$, then there exist a positive constant l_m such that $\int_0^t \mathbf{s}^T \mathbf{s} d\sigma \leq l_m, \forall t \geq 0$. The detailed stability analysis can be found in Wang (2016).

This design approach can also be used for robots with opened control architecture. In this case, a torque controller can be designed using (10) as:

$$\tau = -\mathbf{K}\mathbf{s} + \mathbf{Y}_d(\mathbf{q}, \dot{\mathbf{q}}, \dot{\mathbf{q}}_r, \ddot{\mathbf{q}}_r)\hat{\boldsymbol{\theta}}_d \quad (12)$$

with an update law for dynamic parameters given as:

$$\dot{\hat{\boldsymbol{\theta}}}_d = -\mathbf{L}_d\mathbf{Y}_d(\mathbf{q}, \dot{\mathbf{q}}, \dot{\mathbf{q}}_r, \ddot{\mathbf{q}}_r)\mathbf{s}. \quad (13)$$

The details can be found in Wang (2016).

Summary and Future Directions

Image-based robot control is robust to modelling uncertainty and thus releases users from tedious camera calibration and model identification tasks. To integrate with different robot control architectures, the visual servoing commands can be specified either as joint position or velocity reference inputs or as torque control inputs. It is important to consider the interaction between kinematic control loop and dynamic or inner control loop in the design of the image-based control for the robotic systems with closed control

architecture. Although the separation approach provides a way to design and integrate the kinematic control loop and dynamic control loop, the joint velocity tracking error is required to be square-integrable and bounded. Alleviating this constraint can further widen the potential applications of the image-based control theory to robotic systems.

Most industrial robots do not come with external sensors, and vision systems have to be added and deployed according to various applications. As different cameras and configurations lead to different models, it is still difficult for general users to derive the structure of the Jacobian matrices. Advances in machine intelligence have led to the interests in developing learning techniques for robot systems with unknown structures. Neural networks can be used to estimate the Jacobian matrix, but one issue is that it does not generalize well beyond the training data. Some key challenges are the development of neural network Jacobian control methods that achieve better generalization property and the development of theoretical frameworks in understanding the image-based learning control methods.

Recommended Reading

This entry presents a brief overview of image-based robot control. Several good tutorial papers and the references for pioneer work on kinematic visual servoing can be found in Hutchinson et al. (1996) and Chaumette and Hutchinson (2006). The pioneer result on robot controller design based on Lyapunov method (Slotine and Li 1991) can be found in Takegaki and Arimoto (1981) and more details and references for dynamic image-based robot control can be found in Cheah and Li (2015).

Industrial Cyber-Physical Systems

Alf J. Isaksson

ABB AB, Corporate Research, Västerås, Sweden

Abstract

The notion of cyber-physical systems (CPS) is applicable to many different application domains, for example, the transportation systems and the energy systems. This article deals with industrial CPS, which we define as CPS concepts applied to the process and manufacturing industries. Originating from traditional control systems, the industry is already since a number of years undergoing a major shift toward more connected systems, also reflected in various national initiatives such as Industrie 4.0 in Germany, Smart Manufacturing in the

USA, and Intelligent Manufacturing in China. We first give a brief historic perspective on the industrial automation systems and how that is currently evolving into more general CPS. Then some ongoing trends and future challenges are discussed. This includes the shift toward more autonomous systems and challenges such as analysis of CPS including modelling and cyber-physical security.

Keywords

Cyber-physical systems · Manufacturing · Process automation

Introduction

By definition, cyber-physical systems (CPS) are technical systems characterized by the combination of cyber elements such as communication, computing, and control with processes governed by the laws of the physics. In modern society, they can be found in many different domains, such as energy systems, transportation systems, healthcare applications, as well as process and manufacturing industries. See Allgöwer et al. (2019) for a recent paper that provides an extensive overview of several of these domains.

This article will focus its attention to one of the domains, viz., process and manufacturing industries. This domain was arguably the first application to undergo a development in the direction of CPS. Computer-based supervisory control was first deployed already in the late 1950s. Then, with the introduction of the micro-processor, the first distributed control systems (DCS) were developed in the 1970s.

The history of the Internet runs more or less parallel to that of the distributed control systems, with the first networks being developed in the late 1960s and early 1970s. Despite this, the control system network – often referred to as the operational technology (OT) system – was for many years at the manufacturing site kept separate from the office network, usually referred to as the information technology (IT) system.

Similarly and simultaneously, there has been the development of mobile telecommunication which for the early generations (1G and 2G) had no real impact on industrial automation. It is basically only in the last decade with 3G and 4G and the introduction of smartphones and mobile apps that a convergence of industrial automation, the Internet, and mobile communication has been noticed.

The trend toward improved connectivity and dramatically increased computational power is now rapidly removing the boundaries between OT and IT. The purpose of this article is to give a brief historic account of the development of industrial CPS, as well as to point to some ongoing and future directions of this progress.

Brief History of Industrial CPS

As already mentioned in the introduction, distributed control systems (DCS) were applied in the process industry in the 1970s. In many ways, their architecture has not changed much since. Despite the term “distributed,” they are surprisingly centralized. Typically, measurements of continuous variables, such as temperatures, pressures, flows, etc., are collected via 4–20 mA cables or increasingly with buses such as Foundation Fieldbus or PROFIBUS via I/O units into process computers – often referred to as controllers – that reside in a centralized so-called marshalling room. Then the controllers are connected via a server network to engineering and operator work stations. See Fig. 1 for a typical modern DCS structure.

As indicated to the right in Fig. 1, a modern DCS is integrated with higher levels of the automation hierarchy (see Fig. 2 for the traditional automation pyramid) such as computerized maintenance management systems (CMMS) and enterprise resource planning (ERP). This trend toward being able to access most automation systems from one entry point has led to the introduction of the term Collaborative Process Automation Systems (CPAS) (see the book edited by Hollender 2010). State of the art in many process industries, however, is that the different

Industrial Cyber-Physical Systems, Fig. 1 State-of-the-art distributed control system (ABB's System 800xA – with permission)

Industrial Cyber-Physical Systems, Fig. 2 The traditional automation pyramid

levels of the automation pyramid are still taken care of by different departments using different software, in different geographic locations.

A similar development started even earlier for discrete manufacturing where, starting in the automotive industry, hard-wired relays were replaced by programmable logic controllers (PLC). While a DCS controller usually has both analog and digital inputs and outputs, a PLC instead primarily has digital, i.e., on/off, signals as input and output. However, in recent years, there is a clear convergence where DCS controllers and PLCs have relatively overlapping functionality and performance. PLCs tend to be located nearer to (or integrated into) the machine and thus in fact more distributed. They are often connected to other PLCs in a network and also commonly to a supervisory control and data acquisition (SCADA) system. Hence historically, the hierarchy in Fig. 2 has been equally valid also for manufacturing systems.

Clearly, there is also an increased interplay and integration between CPS for manufacturing and CPS in other domains. For example, Sand and Terwiesch (2013) point out that there is an increasing integration between the process and power automation. In the future, it will be more and more important to take advantage of the fluctuating electricity prices (Mitra et al. 2014), often referred to as industrial demand-side management. Similarly, industrial CPS is of course tightly connected to the transportation systems

since, for example, integrating supply chain and production planning has clear economic benefits (Carlsson et al. 2014).

Summary and Future Directions

An immediate impact of the so-called industrial Internet of Things (IIoT) is that measurement devices, for example, vibration measurements for rotating equipment, may be directly connected to Internet via Bluetooth, WiFi, or soon 5G without necessarily going through the DCS. This opens up entirely new possibilities which have mainly so far been utilized for condition monitoring, and diagnostics. Figure 3 shows a vision, presented in, for example, Monostori et al. (2016) and Isaksson et al. (2018), that from a communication perspective the future factory has no hierarchy and that all products and devices are interconnected in a mesh network.

Even though this vision may not be reached in the short term, it is clear that the information flow will not continue to follow the traditional hierarchy of Fig. 2. ExxonMobil presented in 2016 its visions toward the future automation architecture (see Forbes 2016). They promote increased use of open standards for process automation, which has now been further developed into a first version of a standard O-PASTM by The Open Group (2019).

A somewhat simplified picture of the proposed O-PASTM standard architecture is depicted in

Industrial Cyber-Physical Systems, Fig. 3 Vision on communication in the future factory

Industrial Cyber-Physical Systems, Fig. 4 Potential future control architecture proposed by The Open Group (with permission)

Fig. 4, with color coding indication that the functionality of today's DCS (and PLC) will be distributed between newly defined distributed control nodes (DCN) and a local operation platform (and of course potentially also to a global cloud). At the lowest level, the connection to the common real-time bus could be through a standardized DCN as suggested by The Open Group. However, an even more disruptive scenario – utilizing local intelligence in the devices (commonly referred to as “edge computing”) instead of using separate

DCNs together with 5G communication – would bring us closer to the Industrie 4.0 vision of Fig. 3. This will, however, require a considerable standardization effort to harmonize both communication and control configurations, since devices will be from many different suppliers.

An interesting classification of CPS is introduced in Allgöwer et al. (2019) which points out that a simultaneous development along with two axes is observed (see Fig. 5). Firstly, along the axis of increased computational complexity,

Industrial Cyber-Physical Systems, Fig. 5 Proposed classification of CPS adopted from Allgöwer et al. (2019)

Industrial Cyber-Physical Systems, Fig. 6 Loops in classical control systems (grey) and autonomous systems (red)

we see a trend toward more autonomous systems. This trend began with the development of self-driving cars, but the concept of autonomous systems is now being discussed also in relation to process industries (Gamer et al. 2020). Secondly, with increasing connectivity, we have cyber-physical systems of systems (CPSoS) which in their most advanced form become collaborative.

While a conventional automation system performs predefined instructions within a limited scope of operation, an autonomous system's feedback loop adds an outer loop. Where a classical control loop can be broken down into the phases of sense, analyze, and act, the autonomy applies similar principles but on a more complex level, dealing also with what is not known or foreseen. This can be described in the steps of perceive,

understand, and solve (see Fig. 6), which all may contain artificial intelligence as one important enabling technology (see Gamer et al. (2020) for a more elaborate discussion).

One major challenge of industrial CPS is how to analyze, in advance, the behavior of the system. As control engineers, we are used to being able to analyze stability and to assess, for instance, whether responses will be oscillatory based on dynamic models of the system. CPS are dynamic and hybrid in nature. Even though there are promising approaches, for example, based on temporal logic, the sheer complexity makes analysis complicated, in particular with, as discussed above, increasing use of machine learning components in the closed loop which do not lend themselves easily to theoretical analysis. The fallback solution is then to verify as much as possible the functionality by simulation. In factory automation, the so-called virtual commissioning is already becoming a standard procedure (Lee and Park 2014), and this will eventually be the case also for process automation with models generated automatically from the topology given in process diagrams (Arroyo et al. 2016).

The challenge is then shifted to reducing the modelling effort of each component. More recently, triggered by the notion of a Digital Twin (Negri et al. 2017; Uhlemann et al. 2017), there is a trend toward using models along the entire life cycle of automation. This will require (first principles) physical modelling for basically all components and systems. A vision would be that every product, machine, or device comes with a stored Digital Twin, which would of

course include simulation models also for all control elements. However, this will inevitably need a major standardization effort on modelling formats.

Industrial MPC of Continuous Processes

Mark L. Darby

CMiD Solutions, Houston, TX, USA

Abstract

Model predictive control (MPC) has become the standard approach for implementing constrained, multivariable control of industrial

continuous processes. These are processes designed to operate around nominal steady-state values, which include many of the important processes found in the refining and chemical industries. The following provides an overview of MPC, including its history, major technical developments, and how MPC is applied today in practice. Current and possible future developments are provided.

Industrial MPC of Continuous Processes, Fig. 1
Industrial control and decision hierarchy

Introduction

Model predictive control (MPC) refers to a class of control algorithms that explicitly incorporate a process model for predicting the future response of a plant and relies on optimization as the means of determining control action. At each sample interval, MPC computes a sequence of future plant input signals that optimize future plant behavior. Only the first of the future input sequence is applied to the plant, and the optimization is repeated at subsequent sample intervals.

MPC provides an integrated solution for controlling non-square systems with complex dynamics, interacting variables, and constraints. MPC has become a standard in the continuous process industries, particularly in refining and chemicals, where it has been widely applied for over 25 years. In most commercial MPC products, an embedded steady-state optimizer is cascaded to the MPC controller. The MPC steady-state optimizer determines feasible, optimal settling values of the manipulated and controlled variables. The MPC controller then optimizes the dynamic path to optimal steady-state values.

The scope of an MPC application may include a unit operation such as a distillation column or reactor, or a larger scope such as multiple distillation columns, or a scope that combines

reaction and separation sections of a plant in one controller. MPC is positioned in the control and control decision hierarchy of a processing facility as shown in Fig. 1. The variables associated with MPC consist of manipulated variables (MVs), controlled variables (CVs), and disturbance variables (DVs). CVs include variables normally controlled at a fixed value such as a product impurity and those considered constraints, for example, limits related to capacity or safety that may only be sometimes active. DVs are measurements that are treated as feedforward variables in MPC. The manipulated variables are typically setpoints of underlying PID controllers but may also include valve position signals. Most of the targets and limits are local to the MPC, but others come directly from real-time optimization (if present), or indirectly from planning/scheduling, which are normally translated to the MPC in an open-loop manner by operations personnel.

Linear and nonlinear model forms are found in industrial MPC applications; however, the majority of the applications continue to rely on a linear model, identified from data generated from a dedicated plant test. Nonlinearities that primarily affect system gains are often adequately controlled with linear MPC through gain scheduling or by applying linearizing static transformations. Nonlinear MPC applications tend to be reserved for those applications where nonlinearities

ties are present in both system gains and dynamic responses and the controller must operate at significantly different targets. Most nonlinear MPC applications today have fewer MVs and CVs than linear MPC applications.

Origins and History

MPC has its origins in the process industries in the 1970s. 1978 marked the first published description of predictive control under the name IDCOM, an acronym for Identification and Command (Richalet et al. 1978). A short time later, Cutler and Ramaker (1979) published a predictive control algorithm under the name dynamic matrix control (DMC). Both approaches had been applied industrially for several years before the first publications appeared. These predictive control approaches targeted the more difficult industrial control problems that could not be adequately handled with other methods, either with conventional PID control or with advanced regulatory control (ARC) techniques that rely on single-loop controllers augmented with overrides, feedforwards/decouplers, and custom logic.

The basic idea behind the predictive control approach is shown in Fig. 2 for the case of a single-input single-output, stable system. Future predictions of inputs and outputs are denoted with the hat symbol and shown as dashes; double indexes, $t|k$, indicate future values at time t based on information up to and including time k . The dynamic optimization problem is to bring future predicted outputs ($\hat{y}_{k|k+1}, \dots, \hat{y}_{k|k+P}$) close to a desired trajectory over a prediction horizon, P , by means of a future sequence of inputs ($\hat{u}_{k|k}, \dots, \hat{u}_{k|k+M-1}$) calculated over a control horizon M . The trajectory may be a constant setpoint. When the MPC embeds a steady-state optimizer, future predicted outputs and inputs are driven to their respective steady-state optimums, y^{ss} and u^{ss} . In the general case, the dynamic optimization is performed subject to constraints that may be imposed on future inputs and outputs. Only the first of the future moves is implemented and the optimization is repeated at

the next time instant. Feedback, which accounts for unmeasured disturbances *and* model error, is incorporated by adjusting all future output predictions, prior to the optimization, based on the difference between the output measurement y_k and the previous prediction $\hat{y}_{k|k-1}$, denoted by $d_{k|k}$ (i.e., the prediction error at time instant k). For the case of a stable model, most MPCs shift the entire prediction by $d_{k|k}$. Future predicted values of the outputs depend on both past *and* future values inputs. If no future input changes are made (at time k or after), the model can be used to calculate the future “free” output response, $y_{t,k}^0$, which will ultimately settle at a new steady-state value based on the settling time (or time to steady state of the model, T_{ss}). For the unconstrained case, it is straightforward to show that the optimal result is a linear control law that depends only on the error between the desired trajectory and the free output response.

The predictive approach seemed to contrast with the state-space optimal control method of the time, the linear quadratic regulator (LQR). Later research exposed the similarities to LQR and also internal model control (IMC) (Garcia and Morari 1982), although these techniques did not solve an online optimization problem. Optimization-based control approaches became feasible for industrial applications due to (1) the slower sampling requirements of most industrial control problems (on the order of 1 minute or slower) and the hierarchical implementations in which MPC provides setpoints to lower-level PID controllers which execute on a much faster sample time (on the order of seconds or faster).

Although the basic ideas behind MPC remain, industrial MPC technology has changed considerably since the first formulations in the late 1970s. Qin and Badgwell (2003) describe the enhancements to MPC technology that occurred over the next 20 plus years until the late 1990s. Enhancements since that time are highlighted in Darby and Nikolaou (2012). These improvements to MPC reflect increases in computer processing capability and additional requirements of industry, which have led to increased functionality and tools/techniques to simplify implementation. A summary of the significant enhancements that

have been made to industrial MPC is highlighted below.

Constraints: Posing input and output constraints as linear inequalities, expressed as a function of the future input sequence (Garcia and Morshedi 1986), and solved by a standard quadratic program or an iterative scheme which approximates one.

Two-stage formulations: Limitations of a single objective function led to two-stage formulations to handle MV degrees of freedom (constraint pushing) and steady-state optimization via a linear program (LP).

Integrators. In their native form, impulse and step response models can be applied only to stable systems (in which the impulse response model coefficients approach zero). Extensions to handle integrating variables included embedding a model of the difference of the integrating signal or integrating a fraction of the current prediction error into the future (implying an increasing $|d_{k+j|k}|$ for $j \geq 1$ in Fig. 2). The desired value of an integrator at steady state (e.g., zero slope) can be incorporated into two-stage formulations (see, e.g., Lee and Xiao 2000).

State-space models. The first state-space formulation of MPC, which was introduced in the late 1980s (Marquis and Broustail 1988), allowed MPC to be extended to integrating and unstable processes. It also made use of the Kalman filter which provided additional capability to estimate

plant states and unmeasured disturbances. Later, a state-space MPC offering was developed based on an infinite horizon (for both control and prediction) (Froisy 2006). These state-space approaches provided a connection back to unconstrained LQR theory.

Nonlinear MPC. The first applications of nonlinear MPC, which appeared in the 1990s, were based on neural net models. In these approaches, a linear dynamic model was combined with a neural net model that accounted for static nonlinearity (Demoro et al. 1997; Zhao et al. 2001).

The late 1990s saw the introduction of an industrial nonlinear MPC based on first principles models derived from differential mass and energy balances and reaction kinetic expressions, expressed in differential algebraic equation (DAE) form (Young et al. 2002).

A process where nonlinear MPC is routinely applied is polymer manufacturing.

Identification techniques. Multivariable prediction error techniques are now routinely used. More recently, industrial application of subspace identification methods has appeared, following the development of these algorithms in the 1990s. Subspace methods incorporate the correlation of output measurements in the identification of a multivariable state-space model, which can be used directly in a state-space MPC or converted to an impulse or step response model.

Industrial MPC of Continuous Processes, Fig. 2 Predictive control approach

Testing methods. The 1990s saw increased use of automatic testing methods to generate data for (linear) dynamic model identification using uncorrelated binary signals. Since the 2000, closed-loop testing methods have received considerable attention. The motivation for closed-loop testing is to reduce implementation time and/or effort of the initial implementation as well as the ongoing need to reidentify the model of an industrial application in light of process changes. These closed-loop testing methods, which require a preliminary or existing model, utilize uncorrelated dither signals introduced as either biases to the controller MVs or injected through the steady-state LP or QP, where additional logic or optimization of the test protocol may be performed (Kalafatis et al. 2006; MacArthur and Zhan 2007; Zhu et al. 2012).

Mathematical Formulation

While there are differences in how the MPC problem is formulated and solved, the following general form captures most of the MPC products (Qin and Badgwell 2003), although not all terms may be present in a given product:

$$\min_{\Delta \mathbf{u}} \left[\sum_{j=1}^P \left\| \hat{\mathbf{y}}_{k+j|k} - \mathbf{y}_{k+j|k}^{ref} \right\|_{\mathbf{Q}_j}^2 + \sum_{j=1}^P \left\| \mathbf{s}_{k+j|k} \right\|_{\mathbf{T}_j}^2 + \sum_{j=1}^{M-1} \left\| \hat{\mathbf{u}}_{k+j|k} - \mathbf{u}^{ss} \right\|_{\mathbf{R}_j}^2 + \sum_{j=1}^{M-1} \left\| \Delta \mathbf{u}_{k+j|k} \right\|_{\mathbf{S}_j}^2 \right]$$

subject to

$$\left. \begin{aligned} \hat{\mathbf{x}}_{k+i|k} &= \mathbf{f}(\hat{\mathbf{x}}_{k+i-1|k}, \hat{\mathbf{u}}_{k+i-1|k}), \quad i = 1, \dots, P \\ \hat{\mathbf{y}}_{k+i|k} &= \mathbf{g}(\hat{\mathbf{x}}_{k+i|k}, \hat{\mathbf{u}}_{k+i|k}), \quad i = 1, \dots, P \end{aligned} \right\} \text{Model equations}$$

$$\left. \begin{aligned} \mathbf{y}^{\min} - \mathbf{s}_i &\leq \hat{\mathbf{y}}_{k+i|k} \leq \mathbf{y}^{\max} + \mathbf{s}_i, \quad i = 1, \dots, P \\ \mathbf{s}_j &\geq 0, \quad i = 1, \dots, P \end{aligned} \right\} \text{Output constraints/slacks}$$

$$\left. \begin{aligned} \mathbf{u}^{\min} &\leq \hat{\mathbf{u}}_{k+i|k} \leq \mathbf{u}^{\max}, \quad i = 0, \dots, M-1 \\ -\Delta \mathbf{u}^{\min} &\leq \Delta \mathbf{u}_{k+i|k} \leq \Delta \mathbf{u}^{\max}, \quad i = 0, \dots, M-1 \end{aligned} \right\} \text{Input constraints}$$

where the minimization is performed over the future sequence of inputs $\mathbf{U} \triangleq \hat{\mathbf{u}}_{k|k}, \hat{\mathbf{u}}_{k+1|k}, \dots, \hat{\mathbf{u}}_{k+M-1|k}$. The four terms in the objective function represent conflicting quadratic penalties ($\|\mathbf{x}\|_{\mathbf{A}}^2 \triangleq \mathbf{x}^T \mathbf{A} \mathbf{x}$); the penalty matrices are most always diagonal. The first term penalizes the error relative to a desired reference trajectory (cf. Fig. 2) originating at $\hat{\mathbf{y}}_{k|k}$ and terminating at a desired steady state, $\mathbf{y}^{ss}$; the second term penalizes output constraint violations over the prediction horizon (constraint softening); the third term penalizes inputs deviations from a desired steady state, either manually specified or calculated. The fourth term penalizes input changes as a means of trading off output tracking and input movement (move suppression).

The above formulation applies to both linear and nonlinear MPC. For linear MPCs, except for state-space formulations, there are no state equations, and the outputs in the dynamic model

are a function of only past inputs, such as with the finite step response model.

When a steady-state optimizer is present in the MPC, it provides the steady-state targets for $\mathbf{u}^{ss}$ (in the third quadratic term) and $\mathbf{y}^{ss}$ (in the output reference trajectory). Consider the case of linear MPC with an LP as the steady-state optimizer. The LP is typically formulated as

$$\min_{\Delta \mathbf{u}^{ss}} \mathbf{c}_u^T \Delta \mathbf{u}^{ss} + \mathbf{c}_y^T \Delta \mathbf{y}^{ss} + \mathbf{q}_+^T \mathbf{s}^+ + \mathbf{q}_-^T \mathbf{s}^-$$

subject to

$$\left. \begin{aligned} \Delta \mathbf{y}^{ss} &= \mathbf{G}^{ss} \Delta \mathbf{u}^{ss} \\ \mathbf{u}^{ss} &= \mathbf{u}_{k-1} + \Delta \mathbf{u}^{ss} \\ \mathbf{y}^{ss} &= \mathbf{y}_{k+T_{ss}|k}^0 + \Delta \mathbf{y}^{ss} \end{aligned} \right\} \text{Model equations}$$

$$\mathbf{y}^{\min} - \mathbf{s}^- \leq \mathbf{y}^{ss} \leq \mathbf{y}^{\max} + \mathbf{s}^+ \left\} \text{Output constraints}$$

$$\left. \begin{array}{l} \mathbf{u}^{\min} \leq \mathbf{u}^{ss} \leq \mathbf{u}^{\max} \\ -M\Delta\mathbf{u}^{\max} \leq \mathbf{u}^{ss} \leq M\Delta\mathbf{u}^{\max} \end{array} \right\} \text{Input constraints}$$

$\mathbf{G}^{ss}$ is formed from the gains of the linear dynamic model. Deviations outside minimum and maximum output limits ($\mathbf{s}^-$ and $\mathbf{s}^+$, respectively) are penalized, which provide constraint softening in the event all outputs cannot be simultaneously controlled within limits. The weighting in $\mathbf{q}_-$ and $\mathbf{q}_+$ determine the relative priorities of the output constraints. The input constraints, expressed in terms of $\Delta\mathbf{u}^{\max}$, prevent targets from being passed to the dynamic optimization that cannot be achieved. The resulting solution $-\mathbf{u}^{ss}$ and $\mathbf{y}^{ss}$ provides a consistent, achievable steady state for the dynamic MPC controller. Notice that for inputs, the steady-state delta is applied to the current value and, for outputs, the steady-state delta is applied to the steady-state prediction of the output without future moves, after correcting for the current model error (cf. Fig. 2). If a real-time optimizer is present, its outputs, which may be targets for CVs and/or MVs, are passed to the MPC steady-state optimizer and considered with other objectives but at lower weights or priorities.

Some additional differences or features found in industrial MPCs include:

1-Norm formulations where absolute deviations, instead of quadratic deviations, are penalized.

Use of zone trajectories or “funnels” with small or no penalty applied if predictions remain within the specified zone boundaries.

Use of a minimum movement criterion in either the dynamic or steady-state optimizations, which only lead to MV movement when CV predictions go outside specified limits. This can provide controller robustness to modeling errors.

Multiobjective formulations which solve a series of QP or LP problems instead of a single one and can be applied to the dynamic or steady-state optimizations. In these formulations higher-priority objectives are solved first, followed by lesser-priority objectives with the solution of the higher-priority objectives becoming equality constraints in subsequent optimizations (Maciejowski 2002).

MPC Design

Key design decisions for a given application are the number of MPC controllers and the selection of the MVs, DVs, and CVs for each controller; however, design decisions are not limited to just the MPC layer. The design problem is one of deciding on the best overall structure for the MPC(s) and the regulatory controls, given the control objectives, expected constraints, qualitative knowledge of the expected disturbances, and robustness considerations. It may be that existing measurements are insufficient and additional sensors may be required. In addition, a measurement may not be updated on a time interval consistent with acceptable dynamic control, for example, laboratory measurements and process composition analyzers. In this case, a soft sensor, or inferential estimator, may need to be developed from measurements such as temperature and pressure.

MPC is frequently applied to a major plant unit, with the MVs selected based on their sensitivity to key unit CVs and plant economics. Decisions regarding the number and size of the MPCs for a given application depend on plant objectives, (expected) constraints, and also designer preferences. When the objective is to minimize energy consumption based on fixed or specified feed rate, multiple smaller controllers can be used. In this situation, controllers are normally designed based on the grouping of MVs with the largest effect on the identified CVs, often leading to MPCs designed for individual sections of equipment, such as reactors and distillation columns. When the objective is to maximize feed (or certain products), larger controllers are normally designed, especially if there are multiple constraints that can limit plant throughput. The MPC steady-state LP or QP is ideally suited to solving the throughput maximization problem by utilizing all available MVs. The location of the most limiting constraints can impact the number of MPCs. If the major constraints are near the front end of the plant, one MPC can be designed which connects these constraints with key MVs such as feed rates, and other MPCs designed for the rest of the plant. If the major

constraints are located near the back of the plant, then a single MPC is normally considered. A single MPC has the advantage that throughput changes are better coordinated as a result of the prediction and optimization of future CVs and MVs.

The feed maximization objective is a major reason why MPCs have become larger with the advances in computer processing capability. However, there is generally a higher requirement on model consistency for larger controllers due to the increased number of possible constraint sets against which the MPC can operate. A larger controller can also be harder to implement and understand. This is a reason why some practitioners prefer implementing smaller MPCs at the potential loss of benefits.

MPC Practice

An MPC project is typically implemented in the following sequence:

Pretest and Preliminary MPC Design.
Plant Testing.
Model and Controller Development.
Commissioning.

These tasks apply whether the MPC is linear or nonlinear, but with some differences, primarily model development and in plant testing. In nonlinear MPC, key decisions are related to the model form and level of rigor. Note that with a fundamental model, lower-level PID loops must be included in the model, if the dynamics are significant; this is in contrast to empirical modeling, where the dynamics of the PID loops are embedded in the plant responses. A fundamental model will typically require less plant testing and make use of historical operating data to fit certain model parameters such as heat transfer coefficients and reaction constants. Historical data and/or data from a validated nonlinear static model can also be used to develop nonlinear static models (e.g., neural net) to combine with empirical dynamic models. As mentioned earlier, most industrial applications continue to rely on empirical linear dynamic

models, fit to data from a dedicated plant test. This will be the basis in the following discussion.

In the pretest phase of work, the key activity is one of determining the base-level regulatory controls for MPC, tuning of these controls, and determining if current plant instrumentation is adequate. The existing regulatory control scheme may need to be changed (i.e., modifying the loop pairing) to provide improved disturbance rejection or to better control constraints. It is common to retune a significant number of PID loops. Significant benefits often result from the pretest alone.

A range of testing approaches are used in plant testing for linear MPC, including both manual and automatic (computer-generated) test signal designs, most often in open loop but, increasingly, in closed loop. Most input testing continues to be based on uncorrelated signals, implemented either manually or from computer-generated random sequences. Model accuracy requirements dictate accuracy across a range of frequencies which is achieved by varying the duration of the steps. Model identification runs are made throughout the course of a test to determine when model accuracy is sufficient and a test can be stopped.

In the next phase of work, modeling of the plant is performed. This includes constructing the overall MPC model from individual identification runs, for example, deciding which models are significant and judging the models characteristics (dead times, inverse response settling time, gains) based on engineering/process and a priori knowledge. An important step is analyzing, and adjusting if necessary, the gains of the constructed model to insure the models gains satisfy mass balances and gain ratios do not result in fictitious degrees of freedom (due to model errors) that the steady-state optimizer could exploit. Also included is the development of any required inferentials or soft sensors, typically based on multivariate regression techniques such as principal component regression (PCR), principal component analysis (PCA), and partial least squares (PLS) or sometimes based on a fundamental model.

During controller development, initial controller tuning is performed. This relates to establishing criteria for utilizing available degrees of freedom and setting control variable priorities. In addition, initial tuning values are established for the dynamic control. Steady-state responses corresponding to expected constraint scenarios are analyzed to determine if the controller behaves as expected, especially with respect to the steady-state changes in the manipulated variables.

Commissioning involves testing and tuning the controller against different constraint sets. It is common to modify or revisit model decisions made earlier. In the worst case, control performance may be deemed unacceptable, and the control engineer is forced to revisit earlier decisions such as the base-level regulatory strategy or plant model quality, which would require retesting and reidentification of portions of the plant model. The main commissioning effort typically takes place over a 2- to 3-week period but can vary based on the size and model density of the controller. In reality, commissioning, or, more accurately, controller maintenance, is an ongoing activity. It is important that the operating company has in-house expertise that can be used to answer questions (“why is the controller doing that?”), troubleshoot, and modify the controller to reflect new operating modes and constraint sets.

Current and Future Directions

Future developments are expected to follow extensions of current approaches. We are seeing continued enhancements in the area of closed-loop testing, for example, automatic adjustment of test signal amplitudes, options for closed-loop update of controller models, and the combining of control and identification objectives (“dual” control). A possible enhancement would be to formulate the plant test as a DOE (design of experiments) optimization problem that could, for example, target specific models or model parameters.

In the model identification area, extensions have started to appear which allow constraints to be imposed, for example, on dead times or gains, thus allowing a priori knowledge to be

used. Another important area that has seen recent emphasis, and where more development can be expected, is in monitoring and diagnosis, for example, detecting which submodels of MPC have become inaccurate and significantly impacting control and thus require reidentification.

As mentioned earlier, one of the advantages of state-space modeling is the inherent flexibility to model unmeasured disturbances (i.e., $d_{k+j|j}$, cf. Fig. 2); however, these have not found widespread use in industry. A useful enhancement would be a framework for developing and implementing improved estimators in a convenient and transparent manner that would be applicable to traditional FIR- and FSR-based MPCs.

An area receiving increased attention concerns the coordination of multiple MPCs in a cascade arrangement. Most of the applications and research has focused on a single MPC or multiply distributed MPCs. These newer coordinators which, in the past used the same models as the underlying MPCs, may use different models (possibly nonlinear). In some cases the coordinator is solving higher-level plant objectives that historically were addressed by real-time optimization (RTO).

In the area of nonlinear control, the use of hybrid modeling approaches has increased, for example, integrating known fundamental model relationships with neural net or linear time-varying dynamic models. The motivation is in reducing complexity and controller execution times. The use of hybrid techniques can be expected to further increase, especially if nonlinear control is to be applied more broadly to larger control problems. Even in situations where control with linear MPC is adequate, there may be benefits from the use of hybrid or fundamental models, even if the models are not directly used online. The model could always be linearized for online use. Potential benefits would be quicker model development and model consistency. In the longer term, one can foresee a more general modeling and control environment where the user would not have to be concerned with the distinction between linear and nonlinear models and would be able to easily incorporate known relationships into the controller model.

Abstract

Inertial navigation refers to the calculation of position, velocity, and orientation using measurements from inertial measurement units (IMUs) comprising accelerometers and gyroscopes. In particular, inertial navigation systems integrate forward in time the initial state of the systems replacing dynamic models with IMU measurements. This entry reviews the inertial navigation equations in a compact concise manner. Both the attitude and translational integration equations are presented. The work focuses on strapdown inertial measurement units, with particular emphasis on the algorithms used to compensate for the vehicle's rotation.

Keywords

Inertial measurement unit · Coning correction · Sculling correction · Navigation

Introduction

Inertial navigation has been a critical component of aerospace control systems since their inception. In 1953, Charles S. Draper's space inertial reference equipment famously guided a B-29 bomber from Massachusetts to Los Angeles without the aid of a pilot. This spurred

the development of onboard inertial navigation systems. Following the development of inertial instruments for ballistic missile navigation systems, inertial measurement instruments were used on the Apollo missions for the Saturn V rockets, the Command Module and the Lunar Module.

State feedback controllers often require an observer to reconstruct the state from the observations. In aerospace applications, the controlled state variables usually consist of (at least) position, velocity, and attitude; the process of determining these quantities is referred to as navigation. Typical navigation systems contain models of both the dynamics and the measurements in order to estimate the state. In virtually all inertial navigation systems, the dynamic models of acceleration and angular velocity are replaced by measured quantities (often referred to as “model replacement mode”).

The first inertial navigation systems used in aerospace applications (like Apollo) usually consisted of a gyro-stabilized platform mounted on gimbals designed to remain fixed in inertial space. The orientation of the system with respect to an inertial frame is therefore directly measurable as roll, pitch, and yaw angles at the base of the gimbals. Linear accelerometers are mounted on the stable platform to measure inertial nongravitational accelerations. Simple electronics are used to integrate the acceleration to obtain position and velocity. Alternatively, reference integrating gyros and integrating accelerometers can be both mounted on the stable platform to sense attitude changes and velocity changes, respectively.

Gimbaled inertial measurement units (IMUs) are still used today for high-precision systems, but their cost, weight, and reliance on moving mechanical parts reduce their popularity in favor of strapdown IMUs. The advent of inexpensive and lightweight digital computers has allowed a shift in complexity from hardware to software. In strapdown IMUs, the mechanical gimbals are replaced by strapdown systems, in which sensors are fixed with respect to the vehicle. Measured quantities are now with respect to the rotating vehicle frame, and software/firmware is used to

compensate for the vehicle’s motion. Figure 1 depicts the gimbaled IMU used by Apollo.

Inertial navigation is the process of navigating with respect to an inertial reference frame. This process is most often done by propagating the state of the system forward in time using IMU measurements (i.e., internal measurements). Inertial navigation systems can be aided with external measurements (such as global positioning system or optical measurements) in order to improve the estimation accuracy. With external aiding, the inertial navigation equations are used in the state propagation phase of an estimator such as an extended Kalman filter (EKF).

The goal of this entry is to discuss the inertial navigation equations used in a strapdown system, which is by far the most commonly used type of inertial navigation system today. To maximize the accuracy of the system, measurements are acquired at very high rates, in the order of several hundred or thousands of Hertz, and they are often preprocessed by the sensor’s firmware to accumulate them to a lower rate and to compensate for the rotation of the vehicle; these compensations are called coning (for rotational motion) and sculling (for translational motion). The navigation flight software uses these compensated and accumulated measurements to produce a state estimate at a much lower frequency (typically tens of Hertz).

Inertial Navigation

Strapdown IMUs are advantageous from a cost, weight, and mechanical complexity standpoint, but they are usually less accurate than gimbaled IMUs and introduce different challenges, such as coning and sculling. Coning corrections are sometimes called “non-commutivity rate” corrections. In gimbaled IMUs, the navigation base or platform is stable (sometimes referred to as the “stable member”) with respect to inertial space. In a gimbaled IMU, the inertial attitude is measured directly, and the nongravitational acceleration is measured in inertial coordinates. This is not the case for strapdown IMUs, which measure angular rates and specific accelerations (ones that

Inertial Navigation,

do not include gravity) in a vehicle-fixed coordinate system. These measurements are used by a digital computer that integrates position, velocity, and attitude forward in time. In order to avoid loss of information, rather than sampling and holding the acceleration and angular velocity measurements, they are usually accumulated by the sensor. The accumulated measurements are often internally compensated for repeatable measurement errors with factory calibrated parameters and for the rotation of the vehicle with coning and sculling compensation. These compensations are presented in section “[Coning and Sculling](#)”. The propagation equations using the accumulated and compensated IMU measurements are presented in section “[Inertial Navigation Equations](#)”.

Preliminaries

Vector quantities such as position, velocity, and angular velocity are represented by a lowercase bold symbol. All vectors are column vectors, and the frame in which the vector’s components are expressed is denoted with a superscript: i for

inertial, b for vehicle-fixed (body-fixed), and e for Earth-centered Earth-fixed (ECEF); for example, $\mathbf{r}^i$ is the inertial position. A second superscript to the left of a “dot” indicates the frame in which time derivatives are taken. For example, the inertial time evolution of position $\mathbf{r}$ and velocity $\mathbf{v}$ are

$${}^i\dot{\mathbf{r}}^i(t) = \mathbf{v}^i(t), \quad (1)$$

$${}^i\dot{\mathbf{v}}^i(t) = \mathbf{g}^i(\mathbf{r}^i) + \mathbf{a}^i(t), \quad (2)$$

where $\mathbf{g}(\mathbf{r})$ represents the gravitational acceleration and $\mathbf{a}(t)$ the sum of all nongravitational accelerations. The rotation vector $\boldsymbol{\phi}$ is defined as the product of the Euler angle ϕ and axis $\mathbf{n}$

$$\boldsymbol{\phi}^b = \phi \mathbf{n}^b, \quad (3)$$

and evolves in time according to the Bortz equation Markley and Crassidis (2014)

$$\dot{\phi}^b(t) = \omega^b(t) + \frac{1}{2}\phi^b(t) \times \omega^b(t) + \left[1 - \frac{\phi(t) \sin \phi(t)}{2(1 - \cos \phi(t))}\right] \frac{\phi^b(t) \times (\phi^b(t) \times \omega^b(t))}{\phi(t)^2}, \quad (4)$$

where $\omega^b(t)$ is the body angular velocity with respect to the inertial frame.

The quaternion is defined as

$$\bar{\mathbf{q}} = \begin{bmatrix} \sin(\phi/2) \mathbf{n} \\ \cos(\phi/2) \end{bmatrix} = \begin{bmatrix} \mathbf{q}_v \\ q_s \end{bmatrix}, \quad (5)$$

and describes the rotation by the angle ϕ around the axis $\mathbf{n}$ is a globally non-singular parameterization. We are particularly interested in the inertial-to-body quaternion $\bar{\mathbf{q}}_i^b$ that evolves as

$$\dot{\bar{\mathbf{q}}}_i^b(t) = \frac{1}{2} \begin{bmatrix} \omega^b(t) \\ 0 \end{bmatrix} \otimes \bar{\mathbf{q}}_i^b(t), \quad (6)$$

where $\otimes$ is the modified quaternion multiplication defined as such that quaternions multiply in the same order as attitude matrices (direction cosine matrices).

The direction cosine matrix $\mathbf{T}_i^b$ (i.e., transformation matrix or attitude matrix) transforms vector coordinates from the inertial frame to the body frame and is obtained from the quaternion $\bar{\mathbf{q}}_i^b$ as

$$\mathbf{T}_i^b = \mathbf{T}(\bar{\mathbf{q}}_i^b) = \mathbf{I}_3 - 2q_s[\mathbf{q}_v \times] + 2[\mathbf{q}_v \times]^2, \quad (7)$$

where the skew-symmetric cross product matrix $[\mathbf{w} \times]$ is defined such that for all three-dimensional vectors $\mathbf{w}$ and $\mathbf{v}$, the following equivalence holds: $\mathbf{w} \times \mathbf{v} = [\mathbf{w} \times]\mathbf{v}$.

The continuous-time inertial navigation equations are then given by

$${}^i\dot{\mathbf{r}}^i(t) = \mathbf{v}^i(t), \quad (8)$$

$${}^i\dot{\mathbf{v}}^i(t) = \mathbf{g}^i(\mathbf{r}^i(t)) + \mathbf{T}(\bar{\mathbf{q}}_i^b)^T \mathbf{a}^b(t), \quad (9)$$

$$\dot{\bar{\mathbf{q}}}_i^b(t) = \frac{1}{2} \begin{bmatrix} \omega^b(t) \\ 0 \end{bmatrix} \otimes \bar{\mathbf{q}}_i^b(t). \quad (10)$$

To increase accuracy without integrating the above equations at thousands of Hertz, acceleration and angular velocity are usually not the output of the sensor, rather their accumulated values are

$$\Delta\phi_k^b(i) = \int_{t_k+(i-1)\Delta t_s}^{t_k+i\Delta t_s} \omega^b(\tau) d\tau, \quad (11)$$

$$\Delta\mathbf{v}_k^b(i) = \int_{t_k+(i-1)\Delta t_s}^{t_k+i\Delta t_s} \mathbf{a}^b(\tau) d\tau, \quad (12)$$

where Δt_s is the sensor's sampling time, typically thousands of Hertz. Our first task is to accumulate the measurements into more manageable frequencies to output them to the flight computer while compensating them for the body frame's rotation.

Coning and Sculling

Since the vehicle is, generally, rotating, we cannot simply add many $\Delta\phi_k^b(i)$ and $\Delta\mathbf{v}_k^b(i)$ together because they are expressed in different frames, i.e., at each sample time, the body-fixed frame has a different orientation. Compensating for this effect in the angular velocity is called coning, while performing the same for accelerations is called sculling.

Coning Compensation

The goal is to downsample the gyro measurement while compensating for the frame rotation. Let Δt_k be the IMU output interval; Δt_k is an integer multiple of the IMU's internal sample time Δt_s . The output of the IMU is the total rotation of the body frame over Δt_k , and this rotation is usually expressed via a rotation vector. Therefore, we need to solve the Bortz equation (4) for $\Delta\theta_k^b = \phi^b(t_k + \Delta t_k)$ with initial condition $\phi^b(t_k) = \mathbf{0}$.

The IMU output frequency $1/\Delta t_k$ is usually of the order of hundreds of Hertz; therefore, $\phi(t_k + \Delta t_k)$ is a small quantity, and we can proceed by linearizing the Bortz equation centered at zero

$${}^i\dot{\phi}^b \simeq \omega^b + \frac{1}{2}\phi^b \times \omega^b, \quad \phi(t_k) = \mathbf{0}, \quad (13)$$

and approximating its solution as

$$\begin{aligned}\Delta\theta_k^b &= \phi^b(t_k + \Delta t_k) = \int_0^{\Delta T} \omega^b(t_k + \tau) d\tau \\ &+ \frac{1}{2} \int_0^{\Delta T} \left[\int_0^\tau \omega^b(t_k + \xi) d\xi \right] \\ &\times \omega^b(t_k + \tau) d\tau.\end{aligned}\quad (14)$$

The first of the two terms in this equation is simply given by sum of all $\Delta\theta^b(t_s)$ terms, while the second is called coning correction. Equation (14) is solved by approximating all integrals as sums. Assume $\Delta t_k = N \Delta t_s$ and let $\Delta\phi_k^b(i)$ be the measured attitude increment over the sampling time Δt_s :

$$\begin{aligned}\Delta\phi_k^b(i) &= \phi^b(t_k + i\Delta t_s) \\ &- \phi^b(t_k + (i-1)\Delta t_s), \quad i=1, \dots, N.\end{aligned}$$

Then

$$\begin{aligned}\Delta\theta_k^b &= \sum_{i=1}^N \Delta\phi_k^b(i) \\ &+ \sum_{i=1}^{N-1} \sum_{j=i+1}^N \kappa_{ij} \Delta\phi_k^b(i) \times \Delta\phi_k^b(j).\end{aligned}\quad (15)$$

In a pure coning environment (angular velocity vector rotating at a constant rate), the contribution to the coning integral is independent of absolute time. Thus, taking advantage of this property allows the generalized form of the coning integral to be simplified to

$$\begin{aligned}&\sum_{i=1}^{N-1} \sum_{j=i+1}^N \kappa_{ij} \Delta\phi_k^b(i) \times \Delta\phi_k^b(j) \\ &= \left[\sum_{i=1}^{N-1} \kappa_i \Delta\phi_k^b(i) \right] \times \Delta\phi_k^b(N),\end{aligned}\quad (16)$$

where κ_i are the constant coning coefficients that can be calculated to optimize the results.

In a pure coning environment, the coning coefficients can be evaluated to any order in the coning algorithm. These are the so-called

Ignagni correction coefficients (Ignagni 1996, 1990, 1998) and are shown in Table 1.

Sculling Compensation

Let $\Delta\mathbf{v}_k^b(i)$ be the integrated nongravitational acceleration over one sampling time Δt_s

$$\Delta\mathbf{v}_k^b(i) = \int_{t_k + (i-1)\Delta t_s}^{t_k + i\Delta t_s} \mathbf{a}^b(\tau) d\tau.$$

The goal of sculling is to accumulate the sampled $\Delta\mathbf{v}_k^b(i)$ into lower frequency outputs while compensating for the rotation of the body-fixed frame. As before, the IMU output interval is Δt_k , and $\Delta t_k = N \Delta t_s$. The lower frequency and compensated accelerometer output is denoted by $\Delta\mathbf{v}_k^b$ and can be coordinatized in the body-fixed frame at the beginning, middle, or end of the interval Δt_k . For our purposes, we will develop the equations for the beginning of the interval:

$$\Delta\mathbf{v}_k^b = \int_{t_k}^{t_{k+1}} \mathbf{T}_{b(\tau)}^{b_k} \mathbf{a}^b(\tau) d\tau, \quad (17)$$

where the coning correction is anchored at t_k . The DCM from time t to t_k , where the time interval is small, is given by:

$$\begin{aligned}\mathbf{T}_{b(t)}^{b_k} &= \left(\mathbf{T}_{b_k}^{b(t)} \right)^T = \mathbf{I}_3 + \frac{\sin \phi(t)}{\phi(t)} \left[\phi^b(t) \times \right] \\ &+ \frac{1 - \cos \phi(t)}{\phi(t)^2} \left[\phi^b(t) \times \right]^2 \\ &\approx \mathbf{I}_3 + \left[\phi^b(t) \times \right],\end{aligned}$$

where $\phi^b(t_k) = \mathbf{0}$ and the approximations are valid for small ϕ . Therefore, $\Delta\mathbf{v}_k^b$ could be approximated as

$$\begin{aligned}\Delta\mathbf{v}_k^b &= \int_{t_k}^{t_{k+1}} \mathbf{a}^b(\tau) d\tau \\ &+ \int_{t_k}^{t_{k+1}} \phi^b(\tau) \times \mathbf{a}^b(\tau) d\tau.\end{aligned}\quad (18)$$

A fundamental limitation in the above equation is that the second term does not accurately represent the high-frequency content of the signal. A solu-

κ_7	—	—	—	—	4.802975	2.890517
κ_8	—	—	—	—	—	5.495258

tion is to split Eq. (18) as the sum of two equal components and integrate one of them by parts to more accurately represent the higher frequencies:

$$\begin{aligned} \Delta \mathbf{v}_k^b &= \int_{t_k}^{t_{k+1}} \mathbf{a}^b(\tau) d\tau + \frac{1}{2} \int_{t_k}^{t_{k+1}} \boldsymbol{\phi}^b(\tau) \times \mathbf{a}^b d\tau \\ &+ \frac{1}{2} \Delta \boldsymbol{\theta}_k^b \times \int_{t_k}^{t_{k+1}} \mathbf{a}^b(\tau) d\tau \\ &+ \frac{1}{2} \int_{t_k}^{t_{k+1}} \left[\int_{t_{k-1}}^{\tau} \mathbf{a}^b(\sigma) d\sigma \right] \times \boldsymbol{\omega}^b(\tau) d\tau \end{aligned} \quad (19)$$

$$\begin{aligned} &= \int_{t_k}^{t_{k+1}} \mathbf{a}^b(\tau) d\tau + \frac{1}{2} \Delta \boldsymbol{\theta}_k^b \times \int_{t_k}^{t_{k+1}} \mathbf{a}^b(\tau) d\tau \\ &+ \frac{1}{2} \int_{t_k}^{t_{k+1}} \left[\boldsymbol{\phi}^b(\tau) \times \mathbf{a}^b(\tau) \right. \end{aligned} \quad (20)$$

$$\left. + \left(\int_{t_{k-1}}^{\tau} \mathbf{a}^b(\sigma) d\sigma \right) \times \boldsymbol{\omega}^b(\tau) \right] d\tau. \quad (21)$$

We now discuss each of the terms in Eq. (21) (Savage 1998). The first term represents a pure integration/summation of the accelerometer outputs. The second term represents a rotation correction, accounting for the fact that the frames are rotating. The third term represents the integrated contribution of the high-frequency content of the specific force.

Pure sculling motion is defined as the motion where the angular velocity and the acceleration both rotate at a constant and equal rate. Under pure sculling motion, we can rewrite the integral in Eq. (21) with the same coning coefficients

as before to obtain the sculling computational algorithm:

$$\mathbf{v}_k^b = \sum_{i=1}^K \Delta \mathbf{v}_k^b(i) \quad (22)$$

$$\begin{aligned} \Delta \mathbf{v}_k^b &= \mathbf{v}_k^b + \frac{1}{2} \mathbf{v}_k^b \times \left[\sum_{i=1}^K \Delta \boldsymbol{\phi}_k^b(i) \right] \\ &+ \left[\sum_{i=1}^K \kappa_i \Delta \boldsymbol{\phi}_k^b + (i) \right] \times \mathbf{v}_k^b \\ &+ \left[\sum_{i=1}^K \kappa_i \Delta \mathbf{v}_k^b(i) \right] \times \left[\sum_{i=1}^K \Delta \boldsymbol{\phi}_k^b(i) \right] \end{aligned} \quad (23)$$

where the κ_i are the *coning* correction coefficients shown in Table 1.

Inertial Navigation Equations

The coning and sculling corrections and accumulation of high-rate IMU measurements into more manageable rates are often done by the IMU firmware. The outputs $\Delta \boldsymbol{\theta}_k^b$ and $\Delta \mathbf{v}_k^b$ of the sensor are then used by the flight software to integrate the position and attitude of the vehicle, i.e., to obtain an inertial solution. Different integration schemes can be used. For high-precision positioning, an additional rotation correction can be added to the position propagation equations (Savage 1998); for fast systems (tens of Hertz), it is common to use the following simple equations:

$$\boldsymbol{\alpha}_k^i = \mathbf{g}^i(\mathbf{r}^i(t_k)) \Delta t_k + \mathbf{T}(\bar{\mathbf{q}}_i^b(t_k))^T \Delta \mathbf{v}_k^b, \quad (24)$$

$$\mathbf{r}^i(t_{k+1}) = \mathbf{r}^i(t_k) + \mathbf{v}^i(t_k)\Delta t_k + \frac{1}{2}\boldsymbol{\alpha}_k^i\Delta t_k, \quad (25)$$

$$\mathbf{v}^i(t_{k+1}) = \mathbf{v}^i(t_k) + \boldsymbol{\alpha}_k^i, \quad (26)$$

$$\begin{aligned} \bar{\mathbf{q}}_i^b(t_{k+1}) &= \begin{bmatrix} \sin(\|\Delta\boldsymbol{\theta}_k^b\|/2) & \Delta\boldsymbol{\theta}_k^b/\|\Delta\boldsymbol{\theta}_k^b\| \\ \cos(\|\Delta\boldsymbol{\theta}_k^b\|/2) & \end{bmatrix} \otimes \bar{\mathbf{q}}_i^b(t_k). \end{aligned} \quad (27)$$

Often, it is desired to express state quantities (position, velocity, and attitude) in the ECEF rather than inertial frame. Let $\boldsymbol{\Omega}_E^e$ be Earth's rotation rate in ECEF coordinates. Then the equations in the ECEF frame are given by Titterton and Weston (2004)

$$\begin{aligned} \boldsymbol{\alpha}_k^e &= \mathbf{g}^e(\mathbf{r}^e(t_k))\Delta t_k + \mathbf{T}(\bar{\mathbf{q}}_e^b(t_k))^T \Delta\mathbf{v}_k^b \\ &\quad - 2\boldsymbol{\Omega}_E^e \times \mathbf{v}^e(t_k) - \boldsymbol{\Omega}_E^e \\ &\quad \times (\boldsymbol{\Omega}_E^e \times \mathbf{r}^e(t_k)), \end{aligned} \quad (28)$$

$$\boldsymbol{\vartheta}_k^b = \Delta\boldsymbol{\theta}_k^b - \mathbf{T}(\bar{\mathbf{q}}_e^b(t_k))\boldsymbol{\Omega}_E^e\Delta t_k, \quad (29)$$

$$\mathbf{r}^e(t_{k+1}) = \mathbf{r}^e(t_k) + \mathbf{v}^e(t_k)\Delta t_k + \frac{1}{2}\boldsymbol{\alpha}_k^e\Delta t_k, \quad (30)$$

$$\mathbf{v}^e(t_{k+1}) = \mathbf{v}^e(t_k) + \boldsymbol{\alpha}_k^e, \quad (31)$$

$$\bar{\mathbf{q}}_e^b(t_{k+1}) = \begin{bmatrix} \sin(\|\boldsymbol{\vartheta}_k^b\|/2) & \boldsymbol{\vartheta}_k^b/\|\boldsymbol{\vartheta}_k^b\| \\ \cos(\|\boldsymbol{\vartheta}_k^b\|/2) & \end{bmatrix} \otimes \bar{\mathbf{q}}_e^b(t_k). \quad (32)$$

More accurate higher-order integration methods can also be employed. It is possible to use local Earth frames, e.g., north-east-down, and express the position with latitude, longitude, and altitude. These frames possess singularities at the poles that can be overcome by the wander angle mechanization (Ignagni 2018).

Summary and Future Directions

Strapdown inertial navigation is of fundamental importance for the control of aerospace vehicles. It is used either by itself or in conjunction with external measurements to provide the time propagation equations in estimation algorithms such as the extended Kalman filter. This entry presents both the high rate accumulation equations with coning and sculling corrections and the lower rate navigation equations with integration of position, velocity, and attitude of the vehicle. Only optimal algorithms for pure coning/sculling motion are presented. Other algorithms exist to optimize other types of motion, such as maneuvers or vibrations. The choice of coning/sculling algorithms depends heavily on the application of interest, and it is the subject of continuous research to optimize for desired performance.

Information and Communication Complexity of Networked Control Systems

Serdar Yüksel

Department of Mathematics and Statistics,
Queen's University, Kingston, ON,
Canada

Abstract

Information and communication complexity of a networked control system identifies the minimum amount of information exchange needed between the decision makers (such as encoders, controllers, and actuators) to achieve a certain objective, which may be in terms of reaching a target state or a set, achieving a given expected cost threshold, or minimizing a cost. This formulation does not impose any constraints on the computational requirements to perform the communication or control. Both stochastic and deterministic formulations are considered. We also provide an overview of some recent research results on information structures in decentralized stochastic control and networked control and provide an (admittedly incomplete) literature review.

Keywords

Communication complexity · Networked control · Decentralized stochastic control · Information and control · Information structure design

Introduction

Consider a decentralized stochastic control (or a dynamic team) problem with L control stations (these will be referred to as decision makers and denoted by DMs) under the following dynamics and measurement equations

$$x_{t+1} = f_t(x_t, u_t^1, \dots, u_t^L, w_t), \quad t = 0, 1, \dots \quad (1)$$

$$y_t^i = g_t^i(x_t, u_{t-1}^1, \dots, u_{t-1}^L; v_t^i), \quad (2)$$

where $i \in \{1, 2, \dots, L\} =: \mathcal{L}$ and $x_0, w_{[0, T-1]}, v_{[0, T-1]}^i$ are mutually independent random variables with specified probability distributions. Here, we use the notation $w_{[0, t]} := \{w_s, 0 \leq s \leq t\}$.

The DMs are allowed to exchange limited information, see Fig. 1. The information exchange is facilitated by an encoding protocol $\mathcal{E}$ which is a collection of admissible encoding functions described as follows. Let the information available to DM i at time t be:

$$\mathcal{I}_t^i = \{y_{[1, t]}^i, u_{[1, t-1]}^i, z_{[0, t]}^{j, i}, z_{[0, t]}^{j, i}, j \in \mathcal{L}\},$$

where $z_t^{i, j}$ takes values in some finite set $\mathcal{Z}_t^{i, j}$ and is the information variable transmitted from DM i to DM j at time t generated with

$$\mathbf{z}_t^i = \{z_t^{i, j}, j \in \mathcal{L}\} = \mathcal{E}_t^i(\mathcal{I}_{t-1}^i, u_{t-1}^i, y_t^i), \quad (3)$$

and for $t = 0$, $\mathbf{z}_0^i = \{z_0^{i, j}, j \in \mathcal{L}\} = \mathcal{E}_0^i(y_0^i)$. The control actions are generated with

$$u_t^i = \gamma_t^i(\mathcal{I}_t^i),$$

for all DMs. Define $\log_2(|\mathcal{Z}_t^{i, j}|)$ to be the *communication rate from DM i to DM j at time t* and $\mathcal{R}(\mathbf{z}_{[0, T-1]}) = \sum_{t=0}^{T-1} \sum_{i, j \in \mathcal{L}} \log_2(|\mathcal{Z}_t^{i, j}|)$ to be the *(total) communication rate*. The minimum (total) communication rate over all coding and control policies subject to a design objective is called the *communication complexity* for this objective.

The above is a fixed-rate formulation for communication complexity, since for any two coder

Information and Communication Complexity of Networked Control Systems, Fig. 1

A decentralized networked control system with information exchange between decision makers

outputs, a fixed number of bits is used at any given time. One could also use variable-rate formulations, where, as the measure of the information rate, the cardinality of the message sets is replaced with the Shannon entropy of the exchanged messages. The variable-rate formulation exploits the probabilistic distribution of the system random variables to reduce the rate requirements; see Cover and Thomas (1991). This will be discussed further in section “Connections with Information Theory”.

Communication Complexity for Decentralized Dynamic Optimization

Let $\underline{\mathcal{E}}^i = \{\mathcal{E}_t^i, t \geq 0\}$ and $\underline{\gamma}^i = \{\gamma_t^i, t \geq 0\}$. Under a team-encoding policy $\underline{\mathcal{E}} = \{\underline{\mathcal{E}}^1, \underline{\mathcal{E}}^2, \dots, \underline{\mathcal{E}}^L\}$, and a team-control policy $\underline{\gamma} = \{\underline{\gamma}^1, \underline{\gamma}^2, \dots, \underline{\gamma}^L\}$, let the induced expected cost be

$$E^{\underline{\gamma}, \underline{\mathcal{E}}} \left[\sum_{t=0}^{T-1} c(x_t, u_t^1, u_t^2, \dots, u_t^L) \right]. \quad (4)$$

In networked control, the goal is to minimize (4) over all coding and control policies subject to information constraints and the information structure in the system. Let

$\mathbf{u}_t = \{u_t^1, u_t^2, \dots, u_t^L\}$. The following definition and example are from Yüksel and Başar (2013).

Definition 1 Given a decentralized control problem as above, *team cost-rate function* $C : \mathbb{R} \rightarrow \mathbb{R}$ is

$$C(R) := \inf_{\underline{\gamma}, \underline{\mathcal{E}}} \left\{ E^{\underline{\gamma}, \underline{\mathcal{E}}} \left[\sum_{t=0}^{T-1} c(x_t, \mathbf{u}_t) \right] : \frac{1}{T} \mathcal{R}(\mathbf{z}_{[0, T-1]}) \leq R \right\}.$$

We can define a dual function.

Definition 2 Given a decentralized control problem as above, *team rate-cost function* $R : \mathbb{R} \rightarrow \mathbb{R}$ is

$$R(C) := \inf_{\underline{\gamma}, \underline{\mathcal{E}}} \left\{ \frac{1}{T} \mathcal{R}(\mathbf{z}_{[0, T-1]}) : E^{\underline{\gamma}, \underline{\mathcal{E}}} \left[\sum_{t=0}^{T-1} c(x_t, \mathbf{u}_t) \right] \leq C \right\}.$$

The formulation here can be adjusted to include sequential (iterative) information exchange given a fixed ordering of actions, as opposed to a simultaneous (parallel) information exchange at any given time t . That is, instead of (3), we may have

$$\begin{aligned} \mathbf{z}_t^i &= \{z_t^{i,j}, j \in \{1, 2, \dots, L\}\} \\ &= \mathcal{E}_t^i(\mathcal{I}_{t-1}^i, u_{t-1}^i, y_t^i, \{z_t^{k,i}, k < i\}). \end{aligned} \quad (5)$$

Both to make the discussion more explicit and to show that a sequential (iterative) communication protocol may perform strictly better than an optimal parallel communication protocol given a total rate constraint, we state the following example: Consider the following setup with two DMs. Let x^1, x^2, p be uniformly distributed binary random variables, DM i have access to $y^i, i = 1, 2$, and

$$x = (p, x^1, x^2), \quad y^1 = p, \quad y^2 = (x^1, x^2),$$

and the cost function be

$$\begin{aligned} c(x, u^1, u^2) &= 1_{\{p=0\}}c(x^1, u^1, u^2) \\ &\quad + 1_{\{p=1\}}c(x^2, u^1, u^2), \end{aligned}$$

with

$$c(s, u^1, u^2) = (s - u^1)^2 + (s - u^2)^2.$$

Suppose that we wish to compute the minimum expected cost subject to a total rate of 2 bits that can be exchanged. Under a sequential scheme, if we allow DM 1 to encode y^1 to DM 2 with one bit, then a cost of 0 is achieved since DM 2 knows the relevant information that needs to be transmitted to DM 1, again with one bit: If $p = 0$, x^1 is the relevant random variable with an optimal policy $u^1 = u^2 = x^1$, and if $p = 1$, x^2 is relevant with an optimal policy $u^1 = u^2 = x^2$, and a cost of 0 is achieved. However, if the information exchange is parallel, then DM 2 does not know which state is the relevant one, and it can be shown through information theoretic arguments (Yüksel and Başar 2013, Prop. 12.5.1) that a cost of 0 cannot be achieved under any policy.

The formulation in Definition 1 can also be adjusted to allow for multiple rounds of communication per time stage. Keeping the total rate constant, having multiple rounds can enhance the performance for a class of team problems while keeping the total rate constant.

A formulation relevant to the one in Definition 1 has been considered in Teneketzis (1979) with mutual information constraints; please see section “Connections with Information Theory” for a discussion on such relaxations.

Structural Results on Optimal Policies

Even though obtaining explicit solutions for jointly optimal coding and control problems in its most general setup presented in section “Communication Complexity for Decentralized Dynamic Optimization” is very challenging, it is often very useful to obtain structural results on optimal coding and control policies since through such results one can reduce the search space for optimal policies to a smaller class of functions.

A particularly important special case of the above formulation is the setup with one sensor and one controller who receives information from the sensor, where a control-free or a controlled Markovian source is causally encoded. If the problem described in Definition 1 is for a real-time estimation problem for a Markov source, then the optimal causal fixed-rate coder minimizing any cost function (of the form studied here) uses only the last source symbol and the information at the controller’s memory; see Witsenhausen (1979) and with further refinements in Walrand and Varaiya (1983) which replaced the state with the conditional probability of the state given the information at the controller; a unified view is presented in Teneketzis (2006). These studies considered finite state Markov chains, with real state space and partially observed setup generalizations reported in Yüksel (2013). We refer the reader to Yüksel and Başar (2013, Chp. 10–11), and classical references such as Witsenhausen (1979), Walrand and Varaiya (1983), and more modern studies in Teneketzis (2006), Mahajan and Teneketzis (2009), Yüksel (2019) which presents a separation result involving quantization, estimation, and control, among many other recent references.

For dynamic team problems, such structural results typically follow from the construction of a controlled Markov chain (see Walrand and

Varaiya (1983) and applying tools from stochastic control theory to obtain structural results on optimal coding and control policies (see Nayyar et al. (2014) for a comprehensive construction and Yüksel and Başar (2013) for a review).

Communication Complexity in Decentralized Computation

Yao (1979) significantly influenced the research on communication complexity in distributed computation. This may be viewed as a special case of the setting considered earlier but with finite spaces and in a deterministic, control-free, and an error-free context: Consider two decision makers (DMs) who have access to local variables $x \in \{0, 1\}^n, y \in \{0, 1\}^n$. Given a function f of variables (x, y) , what is the maximum (over all input variables x, y) of the minimum amount of information exchange needed for at least one agent to compute the value of the function?: Let $s(x, y) = \{m_1, m_2, \dots, m_t\}$ be the communication symbols exchanged on input (x, y) during the execution of a communication protocol. Let m_i denote the i th binary message symbol with $|m_i|$ bits. The communication complexity for such a setup is defined as

$$R(f) = \min_{\gamma, \mathcal{E}} \max_{(x, y) \in \{0, 1\}^n \times \{0, 1\}^n} |s(x, y)|, \quad (6)$$

where $|s(x, y)| = \sum_{i=1}^t |m_i|$ and $\mathcal{E}$ is a protocol which dictates the iterative encoding functions as in (5) and γ is a decision policy.

For such problems, obtaining *good* lower bounds is in general challenging. One lower bound for such problems is obtained through the following reasoning: A subset of the form $A \times B$, where A and B are subsets of $\{0, 1\}^n$, is called an *f-monochromatic* rectangle if for every $x \in A, y \in B$, $f(x, y)$ is the same. It can be shown that given any finite message sequence $\{m_1, m_2, \dots, m_t\}$, the set $\{(x, y) : s(x, y) = \{m_1, m_2, \dots, m_t\}\}$ is an *f-monochromatic* rectangle. Hence, to minimize the number of messages, one needs to minimize the number of *f-monochromatic* rectangles which has led

to research in this direction. Upper bounds are typically obtained by explicit constructions. For a comprehensive review, see Kushilevitz and Nisan (2006).

The formulation above is on noise-free distributed computation. When one allows for approximation errors, the conditions are naturally more relaxed. We refer the reader to Tsitsiklis and Luo (1987) and Nemirovsky and Yudin (1983) for information complexity for optimization problems under various formulations and the detailed literature review present in Tsitsiklis and Luo (1987). A sequential setting with an information theoretic approach to the formulation of communication complexity has been considered in Raginsky and Rakhlin (2011). Giridhar and Kumar (2006) discuss distributed computation for a class of symmetric functions under information constraints and present a comprehensive review.

We note finally that for control systems, the discussion takes further aspects into account including a design objective, system dynamics, and the uncertainty in the system variables.

Communication Complexity in Reach-Control

Wong (2009) defines the communication complexity in networked control as follows. Consider a design specification where two DMs wish to steer the state of a dynamical system in finite time. This can be viewed as a setting in (1)–(2) with 4 DMs, where there is iterative communication between a sensor and a DM, and there is no stochastic noise in the system. Given a set of initial states $x_0 \in \mathcal{X}_0$, and finite sets of objective choices for each DM ($\mathcal{A}$ for DM 1, $\mathcal{B}$ for DM 2), the goal is to ensure that (i) there exists a finite time where both DMs know the final state of the system, (ii) the final state satisfies the choices of the DMs, and (iii) the finite time (when the objective is satisfied) is known by the DMs.

The communication complexity for such a system is defined as the infimum over all protocols of the supremum over the triple of initial states and choices of the DMs, such that the above

is satisfied. That is,

$$R(\mathcal{X}_0, \mathcal{A}, \mathcal{B}) = \inf_{\underline{\gamma}, \underline{\mathcal{E}}} \sup_{\alpha, \beta, x_0} R(\underline{\gamma}, \underline{\mathcal{E}}, \alpha, \beta, x_0),$$

where $R(\underline{\gamma}, \underline{\mathcal{E}}, \alpha, \beta, x_0)$ denotes the communication rate under the control and coding functions $\underline{\gamma}, \underline{\mathcal{E}}$, which satisfies the objectives given by the choices α, β and initial condition x_0 .

Wong obtains a cut-set type lower bound: Given a fixed initial state, a lower bound is given by $2D(f)$, where f is a function of the objective choices and $D(f)$ is a variation of $R(f)$ introduced in (6) with the additional property that both DMs know f at the end of the protocol. An upper bound is established by the exchange of the initial states and objective functions also taking into account signaling, that is, the communication through control actions, which is discussed further below in the context of stabilization. Wong and Baillieul (2012) consider a detailed analysis for a real-valued bilinear controlled decentralized system.

Connections with Information Theory

The field of information theory has made foundational contributions to such problems in a variety of contexts. An information theoretic setup typically entails settings where an unboundedly large sequence of messages are encoded and functions of which are to be computed. Such a setting is not applicable in a real-time setting but is very useful for obtaining performance bounds (i.e., good lower bounds on complexity) which can at certain instances be achievable even in a real-time setting. That is, instead of a single-realization of random variables in the setup of (1)–(2), the average performance for a large number of or infinitely many independent realizations/copies for such problems is typically considered.

In such a context, Definitions 1 and 2 can be adjusted so that the communication complexity is computed by mutual information (Cover and Thomas 1991). Replacing the fixed-rate or variable-rate (entropy) constraint in Definition 1 with a mutual information constraint leads to

desirable convexity properties for $C(R)$ and $R(C)$ which does not apply for fixed-rate formulations (Yüksel and Başar 2013, p. 169; György and Linder 2000; György et al. 2008). Such an information theoretic formulation can provide useful lower bounds and desirable analytical properties.

We note here the interesting discussion between decentralized computation and communication provided by Orlitsky and Roche (2001), as well as by Witsenhausen (1976) where a *probability-free* construction is considered and a *zero-error (non-asymptotic and error-free)* computation is considered in the same spirit as in Yao (1979).

Such decentralized computation problems can be viewed as multi-terminal source coding problems with a cost function aligned with the computation objective. Ma and Ishwar (2011) and Gamal and Kim (2012) provide a comprehensive treatment and review of information exchange requirements for computing. Essential in such constructions is the method of *binning* (Wyner and Ziv 1976), which is a key tool in distributed source and channel coding problems. Binning efficiently designates the enumeration of symbols (which can be confused at the receiver in the absence of coding) given the relevant information at the receiver DM from decentralized encoders.

Such problems involve interactive communications as well as multi-terminal coding problems. As mentioned earlier, it is also important to point out that multi-round protocols typically reduce the average rate requirements.

In the particular instance of the general setup noted at the end of section “[Communication Complexity for Decentralized Dynamic Optimization](#)”, where a controlled or control-free Markov source is to be coded across a noisy or noise-free communication channel under information constraints, information theoretic relaxations allow for lower bounds as well as computationally efficient algorithms to obtain such bounds. In the special case of linear systems driven by Gaussian noise, and typically across Gaussian channels, there has been a very significant research activity perhaps

starting from Bansal and Başar (1989), with recent contributions including Tatikonda et al. (2004), Tanaka et al. (2016), Kostina and Hassibi (2019), and Stavrou et al. (2018), among many other references. We also note that information theoretic methods allow for useful lower and upper bounds even for non-Gaussian models; see, e.g., Derpich and Ostergaard (2012).

Communication Complexity in Decentralized Stabilization

An important relevant setting of reach-control is where the target final state is the zero vector: the system is to be stabilized. Consider the following special case of (1)–(2) for an LTI system

$$x_{t+1} = Ax_t + \sum_{j=1}^L B^j u_t^j, \quad y_t^i = C^i x_t \quad t = 0, 1, \dots \quad (7)$$

where $i \in \mathcal{L}$, and it is assumed that the joint system is stabilizable and detectable, but the individual pairs (A, B^i) may not be stabilizable or (A, C^i) may not be detectable. Here, $x_t \in \mathbb{R}^n$ is the state, $u_t^i \in \mathbb{R}^{m_i}$ is the control applied by station i , and $y_t^i \in \mathbb{R}^{p_i}$ is the observation available at station i , all at time t . The initial state x_0 is generated according to a probability distribution supported on a compact set $\mathcal{X}_0 \subset \mathbb{R}^n$. We denote controllable and unobservable subspaces at station i by K^i and N^i and refer to the subspace orthogonal to N^i as the observable subspace at the i th station, denoted by O^i . The information available to station i at time t is $I_t^i = \{y_{[0,t]}^i, u_{[0,t-1]}^i\}$. For such a system (see Fig. 2), it is possible for the controllers to communicate through the plant with the process known as *signaling* which can be used for communication of mode information among the decision makers. Denote by $i \rightarrow j$ the property that DM i can signal to DM j . This holds if and only if $C^j(A)^l B^i \neq 0$, for at least one l , $1 \leq l \leq n$. A directed graph $\mathcal{G}$ among the L stations can be constructed through such a communication relationship.

Information and Communication Complexity of Networked Control Systems, Fig. 2 Decentralized stabilization with multiple controllers

Suppose that A is such that in its Jordan form each Jordan block admits distinct real eigenvalues. Then, a lower bound on the communication complexity (per time stage) for stabilizability is given by $\sum_{|\lambda_i| > 1} \eta_{M_i} \log_2(|\lambda_i|)$, where

$$\eta_{M_i} = \min_{l, m \in \{1, 2, \dots, L\}} \{d(l, m) + 1 : l \rightarrow m, [x^i] \subset O^i \cup O^m, [x^i] \subset K^m\},$$

with $d(l, m)$ denoting the graph distance (number of edges in a shortest path) between DM l and DM m in $\mathcal{G}$ and $[x_i]$ denoting the subspace spanned by x_i . Furthermore, there exist stabilizing coding and control policies whose sum rate is arbitrarily close to this bound. When different Jordan blocks may admit repeated and possibly complex eigenvalues, variations of the result above are applicable. In the special case where there is a centralized controller which receives information from multiple sensors (under stabilizability and joint detectability), even in the presence of unbounded noise (such as Gaussian noise), to achieve asymptotic stability, it suffices to have the average total rate be greater than $\sum_{|\lambda_i| > 1} \log_2(|\lambda_i|)$ (see Johnston and Yüksel 2014, Matveev and Savkin 2008, and Yüksel and

Başar 2013). For the case with a single sensor and single controller, this result has been studied extensively in networked control [see the chapter on *Quantized Control and Data-Rate Constraints* in the Encyclopedia] under a plethora of setups (Nair et al. 2007; Franceschetti and Minero 2014; Kawan 2013; Yüksel 2016).

Information Structures and Their Design in Decentralized Stochastic Control and Some Topological Properties

As observed earlier, a decentralized control system, or a team, consists of a collection of decision makers/agents acting together to optimize a common cost function, but not necessarily sharing all the available information. Teams whose initial states, observations, cost function, or the evolution dynamics are random or are disturbed by some external noise processes are called *stochastic teams*. We now introduce the characterizations as laid out by Witsenhausen, through his *intrinsic model* (Witsenhausen 1975), with the presentation in Yüksel and Saldi (2017). Suppose there is a pre-defined order in which the decision makers act. Such systems are called *sequential systems*. The action and measurement spaces are standard Borel spaces, that is, Borel subsets of complete, separable, and metric spaces. The *intrinsic model* for sequential teams can be defined as follows:

- There exists a collection of *measurable spaces* $\{(\Omega, \mathcal{F}), (\mathbb{U}^i, \mathcal{U}^i), (\mathbb{Y}^i, \mathcal{Y}^i), i \in \mathcal{N}\}$, with $\mathcal{N} = \{1, 2, \dots, N\}$, specifying the system's distinguishable events, and control and measurement spaces. In this model (described in discrete time), any action applied at any given time is regarded as applied by an individual decision maker (DM), who acts only once. The pair $(\Omega, \mathcal{F})$ is a measurable space (on which an underlying probability may be defined). The pair $(\mathbb{U}^i, \mathcal{U}^i)$ denotes the measurable space from which the action, u^i , of decision maker i is selected.

The pair $(\mathbb{Y}^i, \mathcal{Y}^i)$ denotes the measurable observation/measurement space.

- There is a *measurement constraint* to establish the connection between the observation variables and the system's distinguishable events. The $\mathbb{Y}^i$ -valued observation variables are given by $y^i = h^i(\omega, \mathbf{u}^{[1, i-1]})$, where $\mathbf{u}^{[1, i-1]} := \{u^k, k \leq i-1\}$, h^i s are measurable functions and u^k denotes the action of DM k . Hence, y^i induces $\sigma(y^i)$ over $\Omega \times \prod_{k=1}^{i-1} \mathbb{U}^k$.
- The set of admissible control laws $\underline{\gamma} = \{\gamma^1, \gamma^2, \dots, \gamma^N\}$, also called *designs* or *policies*, are measurable control functions, so that $u^i = \gamma^i(y^i)$. Let Γ^i denote the set of all admissible policies for DM i and let $\Gamma = \prod_i \Gamma^i$.
- There is a *probability measure* $\mathbb{P}$ on $(\Omega, \mathcal{F})$ describing the probability space on which the system is defined.

Under this intrinsic model, a sequential team problem is *dynamic* if the information available to at least one DM is affected by the action of at least one other DM. A team problem is *static*, if for every decision maker, the information available is only affected by exogenous disturbances; that is, no other decision maker can affect the information at any given decision maker.

Information structures can additionally be categorized as *classical*, *quasi-classical*, or *nonclassical*. An information structure (IS) $\{y^i, i \in \mathcal{N}\}$ is *classical* if y^i contains all of the information available to DM k for $k < i$. An IS is *quasi-classical* or *partially nested*, if whenever u^k , for some $k < i$, affects y^i through the measurement function h^i , y^i contains y^k . An IS which is not partially nested is *nonclassical*.

Witsenhausen (1988) has shown that a large class of sequential team problems admit an equivalent information structure which is static, under an absolute continuity condition. For partially nested (or quasi-classical) information structures, static reduction of a dynamic team has been studied by Ho and Chu in the specific context of LQG systems (Ho and Chu 1972) and for a class of nonlinear systems satisfying restrictive invertibility properties (Ho and Chu 1973). Thus,

studying static teams is sufficient for investigating a large class of dynamic teams.

Let, as before, $\underline{\gamma} = \{\gamma^1, \dots, \gamma^N\}$, and let $\Gamma = \prod_i^N \Gamma^i$ be the set of admissible policies for the team with N DMs. Assume an expected cost function is defined as

$$J(\underline{\gamma}) = E^\gamma[c(\omega, \mathbf{u})], \quad (8)$$

for some Borel measurable cost function $c : \Omega \times \prod_{k=1}^N \mathbb{U}^k \rightarrow \mathbb{R}$ and where $E^\gamma[c(\omega, \mathbf{u})] := E[c(\omega, \gamma^1(y^1), \dots, \gamma^N(y^N))]$. Here, we have the notation $\mathbf{u} := \{u^i, i \in \mathcal{N}\}$.

Definition 3 For a given stochastic team problem with a given information structure, a policy (strategy) N -tuple $\underline{\gamma}^* := (\gamma^{1*}, \dots, \gamma^{N*}) \in \Gamma$ is *optimal (team-optimal solution)* if

$$J(\underline{\gamma}^*) = \inf_{\underline{\gamma} \in \Gamma} J(\underline{\gamma}) =: J^*.$$

Definition 4 Person-by-person optimal solution. For a given N -DM stochastic team with a fixed information structure, an N -tuple of strategies $\underline{\gamma}^* := (\gamma^{1*}, \dots, \gamma^{N*})$ constitutes a *person-by-person optimal* (pbp optimal) solution if, for all $\beta \in \Gamma^i$ and all $i \in \mathcal{N}$, the following inequalities hold:

$$J^* := J(\underline{\gamma}^*) \leq J(\underline{\gamma}^{-i*}, \beta),$$

where $(\underline{\gamma}^{-i*}, \beta) := (\gamma^{1*}, \dots, \gamma^{(i-1)*}, \beta, \gamma^{(i+1)*}, \dots, \gamma^{N*})$.

On teams with finitely many decision makers, Marschak (1955) studied optimal static teams, and Radner (1962) developed foundational results on optimality, establishing connections between person-by-person optimality, stationarity, and team optimality. Radner's results were generalized in Krainak et al. (1982) by relaxing optimality conditions. A summary of these results is that in the context of static team problems, convexity of the cost function, subject to minor regularity conditions such as continuous differentiability or local finiteness properties, may suffice for the global optimality of person-by-person-optimal solutions. In the particular case for LQG (Linear Quadratic Gaussian) static teams, this result leads to the optimality of

linear policies (Radner 1962), which also applies for dynamic LQG problems under specific information structures (to be discussed further below) (Ho and Chu 1972). These results are applicable for static teams with finite number of decision makers.

Information structures crucially affect whether there exists an optimal team policy or not. We refer the reader to Gupta et al. (2015), Yüksel and Saldi (2017), Charalambous and Ahmed (2017), and Yüksel (2018) for existence and associated geometric properties of information structures (and Yüksel and Başar (2013) for a nonexistence result), Saldi et al. (2017) for rigorous approximation results of optimal stochastic team problems with standard Borel spaces with those that are defined on finite spaces obtained through the quantization of measurement and control action spaces, and Lehrer et al. (2010) and Yüksel and Başar (2013, Chapter 4) for comparison of information structures in decentralized stochastic control.

We refer the reader to Yüksel and Linder (2012) and Yüksel and Başar (2013, Chapter 4) for further topological properties on information structures such as continuity of the optimal expected costs in the information structures and the resulting existence results on optimal information structures and channels/quantizers.

Similar to the discussion in section “**Connections with Information Theory**”, information theoretic relaxations have also been comprehensively studied, where as noted earlier, instead of single realizations, arbitrarily long sequences of random variables under conditional independence and marginal constraints on the empirical measures and mutual information constraints have been considered; these can be used to arrive at lower bounds for optimal decentralized stochastic control problems (Grover et al. 2015; Treust and Oechtering 2018). We refer the reader to Kulkarni and Coleman (2014), Anantharam and Borkar (2007) and Yüksel and Saldi (2017) for further properties on relaxations of information structures both under information theoretic or probabilistic constraints.

Along a further related research direction, information structures with respect to sparsity

constraints have been investigated in a number of publications including Rotkowitz and Lall (2006), Bamieh and Voulgaris (2005), Sabau and Martins (2012), Lin et al. (2012), Lessard and Lall (2011), and Jovanovic (2010). A detailed review for the literature and solution approaches for norm-optimal control as well as optimal stochastic dynamic teams is provided in Mahajan et al. (2012).

Large-Scale Systems and Mean-Field Theory

When the number of decision makers is large, often the analysis becomes significantly simpler under various technical conditions with respect to the structure of the cost function and the coupling among the decision makers. This phenomenon arises in *mean-field equilibrium* problems where the number of decision makers is unbounded (see Huang et al. 2007, 2006; Lasry and Lions 2007): Mean-field games can be viewed as limit models of symmetric non-zero-sum noncooperative N -player games with a mean-field interaction as $N \rightarrow \infty$. The mean-field approach designs policies for both cases of games with infinitely many players, as well as games with very large number of players where the equilibrium policies for the former are shown to be ϵ -equilibria for the latter.

These results, in the context of team problems, involve person-by-person-optimal policies, but these do not guarantee ϵ -global optimality among all policies in general. However, mean-field team problems have also been studied: social optima for mean-field LQG control problems have been considered in Huang et al. (2012) and Wang and Zhang (2017). In Arabneydi and Mahajan (2015), a setup is considered where the decision makers share some information on the mean field in the system, and through showing that the performance of a corresponding centralized system can be attained under a restricted decentralized information structure, global optimality is established. There exist contributions where games with finitely many players are studied, their equilibrium solutions are obtained, and the limit is taken (see, e.g., Fischer 2017; Biswas 2015; Apostathis et al. 2017; Lacker 2016). On a related

direction, Mahajan et al. (2013) and Sanjari and Yüksel (2019) have shown that, under sufficient conditions, a sequence of optimal policies for teams with N number of decision makers as $N \rightarrow \infty$ converges to a team optimal policy for the static team with countably infinite number of decision makers, where the latter establishes the optimality of symmetric (i.e., identical for each DM) policies as well as existence of optimal team policies for both finite and infinite DM setups.

Information Design for Stochastic Games and Networked Control with Non-aligned DMs

We do not have sufficient space to discuss the important subject of stochastic games; however, it would be essential in a short chapter such as this one to at least emphasize that the value of information in stochastic games is a very subtle subject: While the value of information in stochastic teams is always nonnegative, the value of additional information, in the sense of the impact of the additional information on the equilibria values, can be negative. This is due to the fact that equilibrium is a fragile notion arising from consistency conditions in fixed points under *joint* best-response maps and the unilateral best-response of a DM does not lead to a consequential answer on the impact of the additional information on the equilibrium values.

Thus, in the context of information design under information constraints for stochastic games, we note a crucial difference: for team problems, although it is difficult to obtain optimal solutions under general information structures, it is apparent that more information provided to any of the decision makers does not negatively affect the utility of the players. There is also a well-defined partial order of information structures as studied by Blackwell (1953), Lehrer et al. (2010) and Yüksel and Başar (2013). However, for general non-zero-sum game problems, informational aspects are challenging to address; more information can have negative effects on some or even all of the players in a system; see, e.g., Hirschleifer (1971) (see also Peski (2008) for a rather precise result

on comparison of information structures for zero-sum games, where a partial order is established.

In the context of information structure design for games under bit rate constraints, the problems of signaling games and cheap talk are concerned with a class of Bayesian games where a privately informed player (encoder or sender) transmits information (signal) to another player (decoder or receiver). In these problems, the objective functions of the players are not necessarily aligned, unlike the case in classical communication theoretic and control theoretic problems. The cheap talk problem was introduced in the economics literature in Crawford and Sobel (1982), who obtained the striking result that under some technical conditions on the cost functions, the cheap talk problem only admits equilibria that involve quantized encoding policies. This is in significant contrast to the usual communication/information theoretic case where the objective functions are aligned. Therefore, as indicated in Crawford and Sobel (1982), the similarity of players' interests (objective functions) indicates to which extent the information should be revealed by the encoder; Saritaş et al. (2017) extended the analysis for more general sources. We note that, unlike Crawford and Sobel's simultaneous Nash equilibrium formulation, if one considers a Stackelberg formulation (see Başar and Olsder (1999, p.133) for a definition), then the problem would reduce to a modified optimal communication problem since the encoder would be committed a priori; this is known as a *Bayesian persuasion game* (see Kamenica and Gentzkow (2011) and relevant contributions from the control theoretic literature includes Saritaş et al. 2017, Farokhi et al. 2017, Akyol et al. 2017, Sayın et al. 2017, and Treust and Tomala 2018).

Computational Complexity

The focus of this chapter is with regard to information and communication requirements and complexity, and not on computational complexity, which is a rather comprehensive field. Nonetheless, we refer the reader to the computational challenges that have been reflected in the celebrated counterexample of Witsenhausen

(1968). Tsitsiklis and Athans (1985) have observed that from a computational complexity viewpoint, obtaining optimal solutions for a class of such communication protocol design problems is non-tractable. We also note that although finding optimal solutions for finite models has been shown to be NP-complete in Papadimitriou and Tsitsiklis (1986), there exists a plethora of numerical results as well as results rigorously establishing asymptotic optimality of finite/quantized decentralized control policies converging to the optimal solutions (Saldi et al. 2017). A related recent contribution is Olshevsky (2019) which considers problem instances (with arbitrary distributions in the Witsenhausen's counterexample setup) with positive and negative results on complexity. Bernstein et al. (2002) studies the complexity of decentralized stochastic control problems under various setups, in particular, under a decentralized partially observed setup which is aligned with the models considered in this chapter.

Summary

In this text, we discussed the problem of communication complexity in networked control systems. Our analysis considered both cost minimization and controllability/reachability problems subject to information constraints. We also discussed communication complexity in distributed computing as has been studied in the computer science community and provided a brief discussion on the information theoretic approaches for such problems together with structural results. We also provided an overview of some recent research results on information structures in decentralized stochastic control.

Information-Based Multi-agent Systems

Wing Shing Wong¹ and John Baillieul²

¹Department of Information Engineering, The Chinese University of Hong Kong, Shatin, Hong Kong, China

²College of Engineering, Boston University, Boston, MA, USA

Abstract

Multi-agent systems are encountered in nature (animal groups), in various domains of technology (multi-robot networks, mixed robot-human teams), and in various human activities (such as dance and team athletics). Information exchange among agents ranges from being incidentally important to crucial in such systems. Several systems in which information exchange among the agents is either a primary goal or a primary enabler are discussed briefly below. Specific topics include power management in wireless communication networks, data rate constraints, the complexity of distributed control, robotics networks and formation control, action-mediated communication, and multi-objective distributed systems.

Information-Based Control of Networked Systems

► Information-Based Multi-agent Systems

Introduction

The role of information patterns in the decentralized control of multi-agent systems has been

studied in different theoretical contexts for more than five decades. The paper Ho (1972) provides references to early work in this area. While research on distributed decision-making has continued, a large body of recent research on robotic networks has brought new dimensions of geometric aspects of information patterns to the forefront (Bullo et al. 2009). At the same time, machine intelligence, machine learning, machine autonomy, and theories of operation of mixed teams of humans and robots have considerably extended the intellectual frontiers of information-based multi-agent systems (Baillieul et al. 2012). A further important development has been the study of action-mediated communication and the recently articulated theory of *control communication complexity* (Wong and Baillieul 2012). These developments may shed light on nonverbal forms of communication among biological organisms (including humans) and on the intrinsic energy requirements of information processing.

In conventional decentralized control, the control objective is usually well-defined and known to all agents. Multi-agent information-based control encompasses a broader scenario where the objective can be agent-dependent and is not necessarily explicitly announced to all. For illustration, consider the power control problem in wireless communication – one of the earliest engineering systems that can be regarded as multi-agent information-based. It is common that multiple transmitter-receiver communication pairs share the same radio-frequency band and the transmission signals interfere with each other. The power control problem searches for feedback control for each transmitter to set its power level. The goal is for each transmitter to achieve targeted signal-to-interference ratio (SIR) level by using information of the observed levels at the intended receiver only.

A popular version of the power control problem (Foschini and Miljanic 1993) defines each individual objective target level by means of a requirement threshold, known only to the intended transmitter. As SIR measurements naturally reside on a receiver, the observed

SIR needs to be communicated back to the transmitter. For obvious reasons, the bandwidth for such communication is limited. The resulting model fits the bill of multi-agent information-based control. In Sung and Wong (1999), a tri-state power control strategy is proposed so that the power control outputs are either increased or decreased by a fixed dB or no change at all. Convergence of the feedback algorithm was shown using a Lyapunov-like function.

This encyclopedia entry surveys key topics related to multi-agent information-based control systems, including control complexity, control with data rate constraints, robotic networks and formation control, action-mediated communication, and multi-objective distributed systems.

Control Complexity

In information-based distributed control systems, how to efficiently share computational and communication resources is a fundamental issue. One of the earliest investigations on how to schedule communication resources to support a network of sensors and actuators is discussed in Brockett (1995). The concept of *communication sequencing* was introduced to describe how the communication channel is utilized to convey feedback control information in a network consisting of interacting subsystems. In Brockett (1997) the concept of *control attention* was introduced to provide a measure of the complexity of a control law against its performance. As attention is a shared, limited resource, the goal is to find minimum attention control. Another approach to gauge control complexity in a distributed system is by means of the minimum amount of communicated data required to accomplish a given control task.

Control with Data Rate Constraints

A fundamental challenge in any control implementation in which system components communicate with each other over communication links is ensuring that the channel capacity is large enough to deal with the fastest time constants among the system components. In a single

agent system, the so-called data rate theorem has been formulated in various ways to understand the constraints imposed between the sensor and the controller and between the controller and the actuator. Extensions to this fundamental result have been focused on addressing similar problems in the network control system context. Information on such extensions in the distributed control setting can be found in Nair and Evans (2004) and Yüksel and Başar (2007).

Robotic Networks and Formation Control

The defining characteristic of robotic networks within the larger class of multi-agent systems is the centrality of spatial relationships among network nodes. Graph theory has been shown to provide a generally convenient mathematical language in which to describe spatial concepts, and it is the key to understanding spatial rigidity related to the control of formations of autonomous vehicles (Anderson et al. 2008), or in flocking systems (Leonard et al. 2012), or in consensus problems (Su and Huang 2012), or in rendezvous problems (Cortés et al. 2006). For these distributed control research topics, readers can consult other sections in this encyclopedia for a comprehensive reference list.

Much of the recent work on formation control has included information limitation considerations. For consensus problems, for example, Olfati-Saber and Murray (2004) introduced a sensing cost constraint, and in Ren and Beard (2005) information exchange constraints are considered, and in Yu and Wang (2010) communication delays are explicitly modeled.

Action-Mediated Communication

Biological organisms communicate through motion. Examples of this include prides of lions or packs of wolves whose pursuit of prey is a cooperative effort and competitive team athletics in the case of humans. Recent research has been aimed at developing a theoretical foundation of action-mediated communication. Communication protocols for motion-based signaling between mobile robots have been developed (Raghuathan and Baillieul 2009),

and preliminary steps toward a theory of artistic expression through controlled movement in dance have been reported in Baillieul and Özcimder (2012). Motion-based communication of this type involves specially tailored motion description languages in which sequences of motion primitives are assembled with the objective of conveying artistic intent while minimizing the use of limited energy resources in carrying out the movement. These motion primitives constitute the *alphabet* that enables communication, and physical constraints on the motions define the grammatical rules that govern the ways in which motion sequences may be constructed.

Research on action-mediated communication helps illustrate the close connection between control and information theory. Further discussion of the deep connection between the two can be found, for example, in Park and Sahai (2011), which argues for the equivalence between the stabilization of a distributed linear system and the capacity characterization in linear network coding.

Multi-objective Distributive Systems

In a multi-agent system, agents may aim to carry out individual objectives. These objectives can either be cooperatively aligned (such as in a cooperative control setting) or may contend antagonistically (such as in a zero-sum game setting). In either case, a common assumption is that the objective functions are a priori known to all agents. However, in many practical applications, agents do not know the objectives of other agents, at least not precisely. For example, in the power control problem alluded to earlier, the signal-to-interference requirement of a user may be unknown to other users. Yet this does not prevent the possibility of deriving convergent algorithms to allow the joint goals be achieved.

The issue of unknown objective in a multi-agent system is formally analyzed in Wong (2009) via the introduction of choice-based actions. In an open access network, objectives of an individual agent may be known only partially, via the form of a random distribution in some cases. In order to achieve a joint control objective

in general, some communication via the system is required if there is no side communication channel. A basic issue is how to measure the minimum amount of information exchange that is required to perform a specific control task. Motivated by the idea of communication complexity in computer science, the idea of control communication complexity was introduced in Wong (2009), which can provide such a measure. The idea was further applied to nonlinear systems known as the Heisenberg system (or Brockett Integrator) in Wong and Baillieul (2009).

In some special cases, control objectives can be achieved without any communication among the agents. For systems with bilinear input-output mapping, including the Brockett Integrator, it is possible to derive conditions that guarantee this property (Wong and Baillieul 2012). Moreover, for quadratic type of control cost, it is possible to compute the optimal control cost. Similar results can be extended to linear systems as discussed in Liu et al. (2013). This circle of ideas is connected to the so-called *standard parts* problem as investigated in Baillieul and Wong (2009). Another connection is to *correlated equilibrium* problems that have been recently studied by game theorists (Shoham and Leyton-Brown 2009).

Summary and Future Directions

Information based control of multi-agent systems is concerned with the design and effective use of information channels for enabling multiple agents to collaboratively achieve objectives that no single agent could accomplish alone. It focuses in part on systems in which objectives are not explicitly known to individual agents but are nevertheless achievable through the dynamic interactions of the agents. Specific topics discussed above include control communication complexity, control with information constraints, robotic networks, action mediated control, and multi-agent distributed systems. Protocols for information sharing agents can be either cooperative or adversarial or mixtures of both. Research is now needed to develop new theories

of dynamic games that focus on information flows in multi-agent systems.

Information-Theoretic Approaches for Non-classical Information Patterns

Pulkit Grover

Carnegie Mellon University, Pittsburgh, PA, USA

Abstract

The concept of “information structures” in decentralized control is a formalization of the notion of “who knows what and when do they know it.” Even seemingly simple problems with simply stated information structures can be extremely hard to solve. Perhaps the simplest of such unsolved problem is the celebrated Witsenhausen counterexample, formulated by Hans Witsenhausen in 1968. This article discusses how the information structure of the Witsenhausen counterexample makes it hard and how an information-theoretic approach, which explores the knowledge gradient due to a non-classical information pattern, has helped obtain insights into the problem. Applications of these tools to modern cyber-physical systems are also discussed.

Keywords

Team decision theory · Decentralized control · Information theory · Implicit communication

Introduction

Modern control systems often comprise of multiple decentralized control agents that interact over communication channels. What characteristic distinguishes a centralized control problem from a decentralized one? One fundamental difference is a “knowledge gradient”: agents in a decentralized team often observe, and hence know, different things. This observation leads to the idea of *information patterns* (Witsenhausen 1971), a formalization of the notion of “who

Information-Theoretic Approaches for Non-classical Information Patterns, Fig. 1 The evolution of control systems. Modern “networked control systems” (also

called “cyber-physical systems”) are decentralized and networked using communication channels

knows what and when do they know it” (Ho et al. 1978; Mitter and Sahai 1999).

The information pattern is said to be *classical* if all agents in the team receive the same information and have perfect recall (so they do not forget it). What is so special about classical information patterns? For these patterns, the presence of external communication links has no effect on the optimal costs! After all, what could the agents use the communication links for, when there is no knowledge gradient? More interesting, therefore, are the problems for which the information pattern is *non-classical* (Fig. 1). These problems sit at the intersection of communication and control: *communication between agents* can help reduce the knowledge differential that exists between them, helping them perform the *control* task. Intellectually and practically, the concept of non-classical information patterns motivates a lot of formulations at the control-communication intersection. Many of these formulations – including some discussed in this encyclopedia (e.g., Nair 2014; Kawan 2014; Bushnell 2014; Hespanha 2014; Yuksel 2014) – intellectually ask the question: for a realistic channel that is constrained by noise, bandwidth, and speed, what is the optimal communication *and* control strategy?

One could ask the question of optimal control strategy even for decentralized control problems where no external channel is available to bridge

this knowledge gradient. Why could these problems be of interest? First, these problems are limiting cases of control with communication constraints. Second, and perhaps more importantly, they bring out an interesting possibility that can allow the agents to “communicate,” i.e., exchange information, *even when the external channel is absent*. It is possible to use control actions to *communicate* through changing the system state! We now introduce this form of communication using a simple toy example.

Communicating Using Actions: An Example

To gain intuition into when communication using actions could be useful, consider the inverted pendulum example shown in Fig. 2. The goal of the two agents is to bring the pendulum as close to the origin as possible. Both controllers have their strengths and weaknesses. The “weak” controller C_w has little energy but has perfect state observations. On the other hand, the “blurry” controller C_b has infinite energy but noisy observations. They act one after the other, and their goal is to move the pendulum close to the center from any initial state. The information structure of the problem is non-classical: the C_w , but not C_b , knows the initial state of the pendulum, and C_w

Information-Theoretic Approaches for Non-classical Information Patterns, Fig. 2 Two controllers, with their respective strengths and weaknesses, attempting to bring an inverted pendulum close to the center. Also shown (using green “+” signs) are possible quantization points chosen by the controllers for a quantization-based control strategy

does not know the precise (noisy) observation of C_b using which C_b takes actions.

A possible strategy: A little thought reveals an interesting strategy – the weak controller, having perfect observations, can move the state to the closest of some pre-decided points in space, effectively *quantizing* the state. If these quantization points are sufficiently far from each other, they can be estimated accurately (through the noise) by the blurry controller, which can then use its energy to push the pendulum all the way to zero. In this way, the weak controller expends little energy but is able to “communicate” the state through the noise to the blurry controller, by making it take values on a finite set. Once the blurry controller has received the state through the noise, it can use its infinite energy to push the state to zero.

The Witsenhausen Counterexample

The above two-controller inverted pendulum example is, in fact, motivated by what is now known as “the Witsenhausen counterexample,” formulated by Hans Witsenhausen in 1968 (Witsenhausen 1968) (see Fig. 3). In the counterexample, two controllers (denoted

Information-Theoretic Approaches for Non-classical Information Patterns, Fig. 3 The Witsenhausen counterexample is a deceptively simple two-time-step two-controller decentralized control problem. The weak and the blurry controllers, C_w and C_b , act in a sequential manner

here by C_w for “weak” and C_b for “blurry”) act one after the other in two time-steps to minimize a quadratic cost function. The system state is denoted by x_t , where t is the time index. u_w and u_b denote the inputs generated by the two controllers. The cost function is $k^2 \mathbb{E}[u_w^2] + \mathbb{E}[x_2^2]$ for some constant k . The initial state x_0 and the noise z at the input of the blurry controller are assumed to be Gaussian distributed and independent, with variances σ_0^2 and 1, respectively. The problem is a “linear-quadratic-Gaussian” (LQG) problem, i.e., the state evolution is linear, the costs are quadratic, and the primitive random variables are Gaussian.

Why is the problem called a “counterexample”? The traditional “certainty-equivalence” principle (Bertsekas 1995) shows that for all centralized LQG problems, linear control laws are optimal. Witsenhausen (1968) provided a nonlinear strategy for the Witsenhausen problem which outperforms all linear strategies. Thus, the counterexample showed that the certainty-equivalence doctrine does not extend to decentralized control.

What is this strategy of Witsenhausen that outperforms all linear strategies? It is, in fact, a quantization-based strategy, as suggested in our inverted pendulum story above. Further, it was shown by Mitter and Sahai (1999) that multi-point quantization strategies can outperform linear strategies by an arbitrarily large factor. Considering the simplicity of the counterexample, this observation makes the problem very

Information-Theoretic Approaches for Non-classical Information Patterns, Fig. 4 The optimization solution of Baglietto et al. (1997) for $k^2 = 0.5$, $\sigma_0^2 = 5$. The information-theoretic strategy of “dirty-paper coding” (Costa 1983) also yields the same curve (Grover and Sahai 2010a)

important in decentralized control. This simple two-time-step two-controller LQG problem needs to be understood to have any hope of understanding larger and more complex problems.

While the optimal costs for the problem are still unknown, (Even though it is known that an optimal strategy exists (Witsenhausen 1968; Wu and Verdú 2011)) there exists a wealth of understanding of the counterexample that has helped address more complicated problems. A body of work, starting with that of Baglietto et al. (1997), numerically obtained solutions that could be close to optimal (although there is no mathematical proof thereof; indeed, there are many local minima that make this search difficult Subramanian et al. 2018). All these solutions have a consistent form (illustrated in Fig. 4), with slight improvements in the optimal cost. Because the discrete version of the problem, appropriately relaxed, is known to be NP-complete (Papadimitriou and Tsitsiklis 1986), this approach cannot be used to understand the entire parameter space, and hence has focused on one point: $k^2 = 0.5$, $\sigma_0^2 = 5$. Nevertheless, the approach has proven to be insightful: a recent

information-theoretic body of work shows that the strategies of Fig. 4 can be thought of as information-theoretic strategies of “dirty-paper coding” (Costa 1983) that is related to the idea of embedding information in the state. The question here is: how do we embed the information about the state *in the state itself*?

An information-theoretic view of the counterexample This information-theoretic approach that culminated in Grover et al. (2013) also obtained the first approximately optimal solutions to the Witsenhausen counterexample, as well as its vector extensions. The result is established by analyzing information flows in the counterexample that work toward minimizing the knowledge gradient, effectively an information pattern in which C_w can predict the observation of C_b more precisely. The analysis provides *an information-theoretic lower bound on cost that holds irrespective of what strategy is used*. For the original problem, this characterizes the optimal costs (with associated strategies) within a factor of 8 for all problem parameters (i.e., k and σ_0^2). For any finite-length extension, uniform-finite-ratio approximations also exist (Grover et al. 2013). The asymptotically infinite-length extension has been solved *exactly* (Choudhuri and Mitra 2012).

The information-theoretic strategies build on the idea of “dirty-paper coding” (DPC) (Costa 1983) in information theory and utilize a combination of DPC and linear strategies. These strategies, termed “slopy quantization”, were recently shown to be locally optimal (Ajorlou and Jadbabaie 2016) and resemble the strategies obtained numerically in Baglietto et al. (1997).

The problem has also driven delineation of decentralized LQG control problems with optimal linear solutions and those with nonlinear optimal solutions. This led to development and understanding of many variations of the counterexample (Bansal and Başar 1987; Ho et al. 1978; Rotkowitz et al. 2006; Başar 2008) and understanding that can extend to larger decentralized control problems. More recent work shows that the promise of the Witsenhausen counterexample was not a misplaced one: the

information-theoretic approach that provides approximately optimal solutions to the counterexample (Grover et al. 2013) yields solutions to other more complex (e.g., multi-controller, more time-steps) problems as well (Park and Sahai 2012; Grover 2010).

Applications, Summary, and Future Directions

One might ask if this two-agent problem already provides insights on practical applications. As the era of cyber-physical systems arrives, we believe that the applications of decentralized control will only increase. One particular issue of interest is synchronization, which, abstractly, requires the state of two systems to be aligned in state space and time. This requires accurate estimates of states of each agents to be available to other agents – if the agents have noisy or blurry observations, limited capacity channels connecting them, or a limited resource clock synchronizing them. For example, in Shi et al. (2016), the authors observe that hardware implementation of certain neuromorphic architectures suffers from phase-synchronization issues. They arrive at quantization-based strategies, in which the phase itself is quantized, to attain reliable estimation. Similarly, in a robotics company called “Kiva Systems”, locations of robots are quantized to enable multiple robots to work in the same warehouse without collisions (). In general, wherever extremely precise estimates of states are required, and state editing is possible, quantization of the state might be a useful approach but can be easily overlooked. It might also be possible to improve it using dirty-paper coding-type strategies developed in the literature. When communication channels are present, one can optimize use of both implicit and explicit channels (Grover and Sahai 2010b).

This information-theoretic approach is promising for larger decentralized control problems as well. It is now important to explore what is the simplest decentralized control problem that cannot be solved (exactly or approximately) using ideas developed for the

counterexample. In this manner, the Witsenhausen counterexample can provide a platform to unify the more modern (i.e., external-channel centric approaches; see Nair (2014), Kawan (2014), Bushnell (2014), Hespanha (2014), and Yuksel (2014) in the encyclopedia) with the more classical decentralized LQG problems, leading to intellectually enriching and practically useful formulations.

Input-to-State Stability

Eduardo D. Sontag

Departments of Bioengineering and Electrical and Computer Engineering, Northeastern University, Boston, MA, USA

Abstract

The notion of input-to-state stability (ISS) qualitatively describes stability of the mapping from initial states and inputs to internal states (and more generally outputs). The entry focuses on the definition of ISS and a discussion of equivalent characterizations.

Keywords

Input-to-state stability · Lyapunov functions · Dissipation · Asymptotic stability

Introduction

We consider here systems with inputs in the usual sense of control theory:

$$\dot{x}(t) = f(x(t), u(t))$$

(the arguments “ t ” is often omitted). There are n state variables and m input channels. States $x(t)$ take values in Euclidean space $\mathbb{R}^n$, and the inputs (also called “controls” or “disturbances” depending on the context) are measurable locally essentially bounded maps $u(\cdot) : [0, \infty) \rightarrow \mathbb{R}^m$. The map $f : \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}^n$ is assumed to be locally Lipschitz with $f(0, 0) = 0$. The solution, defined on some maximal interval

$[0, t_{\max}(x^0, u))$, for each initial state x^0 and input u , is denoted as $x(t, x^0, u)$, and in particular, for systems with no inputs $\dot{x}(t) = f(x(t))$, just as $x(t, x^0)$. The *zero-system* associated with $\dot{x} = f(x, u)$ is by definition the system with no inputs $\dot{x} = f(x, 0)$. Euclidean norm is written as $|x|$. For a function of time, typically an input or a state trajectory, $\|u\|$, or $\|u\|_\infty$ for emphasis, is the (essential) supremum or “sup” norm (possibly $+\infty$, if u is not bounded). The norm of the restriction of a signal to an interval I is denoted by $\|u_I\|_\infty$ (or just $\|u_I\|$).

Input-to-State Stability

It is convenient to introduce “comparison functions” to quantify stability. A *class $\mathcal{K}_\infty$ function* is a function $\alpha : \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}_{\geq 0}$ which is continuous, strictly increasing, and unbounded and satisfies $\alpha(0) = 0$, and a *class $\mathcal{KL}$ function* is a function $\beta : \mathbb{R}_{\geq 0} \times \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}_{\geq 0}$ such that $\beta(\cdot, t) \in \mathcal{K}_\infty$ for each t and $\beta(r, t)$ decreases to zero as $t \rightarrow \infty$, for each fixed r .

For a system with no inputs $\dot{x} = f(x)$, there is a well-known notion of global asymptotic stability (for short from now on, *GAS* or “*0-GAS*” when referring to the zero-system $\dot{x} = f(x, 0)$ associated with a given system with inputs $\dot{x} = f(x, u)$) due to Lyapunov, and usually defined in “ ε - δ ” terms. It is an easy exercise to show that this standard definition is in fact equivalent to the following statement:

$$(\exists \beta \in \mathcal{KL}) \quad |x(t, x^0)| \leq \beta(|x^0|, t) \quad \forall x^0, \forall t \geq 0.$$

The notion of input-to-state stability (ISS) was introduced in Sontag (1989), and it provides theoretical concepts used to describe stability features of a mapping $(u(\cdot), x(0)) \mapsto x(\cdot)$ that sends initial states and input functions into states (or, more generally, outputs). Prominent among these features are that inputs that are bounded, “eventually small,” “integrally small,” or convergent, should lead to outputs with the respective property. In addition, ISS and related notions quantify in what

manner initial states affect transient behavior. The formal definition is as follows.

A system is said to be *input to state stable* (ISS) if there exist some $\beta \in \mathcal{KL}$ and $\gamma \in \mathcal{K}_\infty$ such that

$$|x(t)| \leq \beta(|x^0|, t) + \gamma(\|u\|_\infty) \quad (\text{ISS})$$

holds for all solutions (meaning that the estimate is valid for all inputs $u(\cdot)$, all initial conditions x^0 , and all $t \geq 0$). Note that the supremum $\sup_{s \in [0, t]} \gamma(|u(s)|)$ over the interval $[0, t]$ is the same as $\gamma(\|u_{[0, t]}\|_\infty) = \gamma(\sup_{s \in [0, t]} |u(s)|)$, because the function γ is increasing, so one may replace this term by $\gamma(\|u\|_\infty)$, where $\|u\|_\infty = \sup_{s \in [0, \infty)} \gamma(|u(s)|)$ is the sup norm of the input, because the solution $x(t)$ depends only on values $u(s)$, $s \leq t$ (so, one could equally well consider the input that has values $\equiv 0$ for all $s > t$).

Since, in general, $\max\{a, b\} \leq a + b \leq \max\{2a, 2b\}$, one can restate the ISS condition in a slightly different manner, namely, asking for the existence of some $\beta \in \mathcal{KL}$ and $\gamma \in \mathcal{K}_\infty$ (in general different from the ones in the ISS definition) such that

$$|x(t)| \leq \max\{\beta(|x^0|, t), \gamma(\|u\|_\infty)\}$$

holds for all solutions. Such redefinitions, using “max” instead of sum, are also possible for each of the other concepts to be introduced later.

Intuitively, the definition of ISS requires that, for t large, the size of the state must be bounded by some function of the sup norm – that is to say, the amplitude – of inputs (because $\beta(|x^0|, t) \rightarrow 0$ as $t \rightarrow \infty$). On the other hand, the $\beta(|x^0|, 0)$ term may dominate for small t , and this serves to quantify the magnitude of the transient (overshoot) behavior as a function of the size of the initial state x^0 (Fig. 1). The *ISS superposition theorem*, discussed later, shows that ISS is, in a precise mathematical sense, the conjunction of two properties, one of them dealing with asymptotic bounds on $|x^0|$ as a function of the magnitude of the input and the other one providing a transient term obtained when one ignores inputs.

For internally stable linear systems $\dot{x} = Ax + Bu$, the variation of parameters formula

Input-to-State Stability, Fig. 1 ISS combines overshoot and asymptotic behavior

gives immediately the following inequality:

$$|x(t)| \leq \beta(t) |x^0| + \gamma \|u\|_\infty,$$

where

$$\beta(t) = \|e^{tA}\| \rightarrow 0 \text{ and}$$

$$\gamma = \|B\| \int_0^\infty \|e^{sA}\| ds < \infty.$$

This is a particular case of the ISS estimate, $|x(t)| \leq \beta(|x^0|, t) + \gamma (\|u\|_\infty)$, with linear comparison functions.

Feedback Redesign

The notion of ISS arose originally as a way to precisely formulate, and then answer, the following question. Suppose that, as in many problems in control theory, a system $\dot{x} = f(x, u)$ has been stabilized by means of a feedback law $u = k(x)$ (Fig. 2), that is to say, k was chosen such that the origin of the closed-loop system $\dot{x} = f(x, k(x))$ is globally asymptotically stable. (See, e.g., Sontag 1999 for a discussion of mathematical aspects of state feedback stabilization.) Typically, the design of k was performed by ignoring the effect of possible *input disturbances* $d(\cdot)$ (also called *actuator disturbances*). These “disturbances” might represent true noise or perhaps errors in the calculation of the value $k(x)$

Input-to-State Stability, Fig. 2 Feedback stabilization, closed-loop system $\dot{x} = f(x, k(x))$

Input-to-State Stability, Fig. 3 Actuator disturbances, closed-loop system $\dot{x} = f(x, k(x) + d)$

by a physical controller or modeling uncertainty in the controller or the system itself. What is the effect of considering disturbances? In order to analyze the problem, d is incorporated into the model, and one studies the new system $\dot{x} = f(x, k(x) + d)$, where d is seen as an input (Fig. 3). One may then ask what is the effect of d on the behavior of the system. Disturbances d may well destabilize the system, and the problem may arise even when using a routine technique for control design, feedback linearization. To appreciate this issue, take the following very simple example. Given is the system

$$\dot{x} = f(x, u) = x + (x^2 + 1)u.$$

In order to stabilize it, substitute $u = \frac{\tilde{u}}{x^2 + 1}$ (a preliminary feedback transformation), rendering the system linear with respect to the new input $\tilde{u}$: $\dot{x} = x + \tilde{u}$, and then use $\tilde{u} = -2x$ in order to obtain the closed-loop system $\dot{x} = -x$. In other words, in terms of the original input u , the feedback law is

$$k(x) = \frac{-2x}{x^2 + 1}$$

so that $f(x, k(x)) = -x$. This is a GAS system. The effect of the disturbance input d is analyzed

as follows. The system $\dot{x} = f(x, k(x) + d)$ is:

$$\dot{x} = -x + (x^2 + 1)d.$$

This system has solutions which diverge to infinity even for inputs d that converge to zero; moreover, the constant input $d \equiv 1$ results in solutions that explode in finite time. Thus $k(x) = \frac{-2x}{x^2+1}$ was not a good feedback law, in the sense that its performance degraded drastically once actuator disturbances were taken into account.

The key observation for what follows is that if one adds a correction term “ $-x$ ” to the above formula for $k(x)$, so that now:

$$\tilde{k}(x) = \frac{-2x}{x^2 + 1} - x$$

then the system $\dot{x} = f(x, \tilde{k}(x) + d)$ with disturbance d as input becomes, instead:

$$\dot{x} = -2x - x^3 + (x^2 + 1)d$$

and this system is much better behaved: it is still GAS when there are no disturbances (it reduces to $\dot{x} = -2x - x^3$) but, in addition, it is ISS (easy to verify directly, or appealing to some of the characterizations mentioned later). Intuitively, for large x , the term $-x^3$ serves to dominate the term $(x^2 + 1)d$, for all bounded disturbances $d(\cdot)$, and this prevents the state from getting too large.

This example is an instance of a general result, which says that, whenever there is some feedback law that stabilizes a system, there is also a (possibly different) feedback so that the system with external input d is ISS.

Theorem 1 (Sontag 1989) *Consider a system affine in controls*

$$\begin{aligned} \dot{x} &= f(x, u) \\ &= g_0(x) + \sum_{i=1}^m u_i g_i(x) \quad (g_0(0) = 0) \end{aligned}$$

and suppose that there is some differentiable feedback law $u = k(x)$ so that

$$\dot{x} = f(x, k(x))$$

has $x = 0$ as a GAS equilibrium. Then, there is a feedback law $u = \tilde{k}(x)$ such that

$$\dot{x} = f(x, \tilde{k}(x) + d)$$

is ISS with input $d(\cdot)$

The reader is referred to the book Krstić et al. (1995), and the references given later, for many further developments on the subjects of recursive feedback design, the “back-stepping” approach, and other far-reaching extensions.

Equivalences for ISS

This section reviews results that show that ISS is equivalent to several other notions, including asymptotic gain, existence of robustness margins, dissipativity, and an energy-like stability estimate.

Nonlinear Superposition Principle

Clearly, if a system is ISS, then the system with no inputs $\dot{x} = f(x, 0)$ is GAS: the term $\|u\|_\infty$ vanishes, leaving precisely the GAS property. In particular, then, the system $\dot{x} = f(x, u)$ is *0-stable*, meaning that the origin of the system without inputs $\dot{x} = f(x, 0)$ is stable in the sense of Lyapunov: for each $\varepsilon > 0$, there is some $\delta > 0$ such that $|x^0| < \delta$ implies $|x(t, x^0)| < \varepsilon$. (In comparison-function language, one can restate 0-stability as there is some $\gamma \in \mathcal{K}$ such that $|x(t, x^0)| \leq \gamma(|x^0|)$ holds for all small x^0 .)

On the other hand, since $\beta(|x^0|, t) \rightarrow 0$ as $t \rightarrow \infty$, for t large one has that the first term in the ISS estimate $|x(t)| \leq \max\{\beta(|x^0|, t), \gamma(\|u\|_\infty)\}$ vanishes. Thus an ISS system satisfies the following *asymptotic gain property* (“AG”): there is some $\gamma \in \mathcal{K}_\infty$ so that:

$$\overline{\lim}_{t \rightarrow +\infty} |x(t, x^0, u)| \leq \gamma(\|u\|_\infty) \quad \forall x^0, u(\cdot) \quad (\text{AG})$$

(see Fig. 4). In words, for all large enough t , the trajectory exists, and it gets arbitrarily close to a sphere whose radius is proportional, in a

Input-to-State Stability, Fig. 4 Asymptotic gain property

possibly nonlinear way quantified by the function γ , to the amplitude of the input. In the language of robust control, the estimate (AG) would be called an “ultimate boundedness” condition; it is a generalization of attractivity (all trajectories converge to zero, for a system $\dot{x} = f(x)$ with no inputs) to the case of systems with inputs; the “limsup” is required since the limit of $x(t)$ as $t \rightarrow \infty$ may well not exist. From now on (and analogously when defining other properties), we will just say “the system is AG” instead of the more cumbersome “satisfies the AG property”.

Observe that, since only large values of t matter in the limsup, one can equally well consider merely tails of the input u when computing its sup norm. In other words, one may replace $\gamma(\|u\|_\infty)$ by $\gamma(\lim_{t \rightarrow +\infty} |u(t)|)$, or (since γ is increasing), $\lim_{t \rightarrow +\infty} \gamma(|u(t)|)$.

The surprising fact is that these two necessary conditions are also sufficient. This is summarized by the *ISS superposition theorem*:

Theorem 2 (Sontag and Wang 1996) *A system is ISS if and only if it is 0-stable and AG.*

A minor variation of the above superposition theorem is as follows. Let us consider the *limit property (LIM)*:

$$\inf_{t \geq 0} |x(t, x^0, u)| \leq \gamma(\|u\|_\infty) \quad \forall x^0, u(\cdot) \quad (\text{LIM})$$

(for some $\gamma \in \mathcal{K}_\infty$).

Theorem 3 (Sontag and Wang 1996) *A system is ISS if and only if it is 0-stable and LIM.*

Robust Stability

In this entry, a system is said to be *robustly stable* if it admits a *margin of stability* ρ , that is, a smooth function $\rho \in \mathcal{K}_\infty$ so the system

$$\dot{x} = g(x, d) := f(x, d\rho(|x|))$$

is GAS uniformly in this sense: for some $\beta \in \mathcal{KL}$,

$$|x(t, x^0, d)| \leq \beta(|x^0|, t)$$

for all possible $d(\cdot) : [0, \infty) \rightarrow [-1, 1]^m$. An alternative way to interpret this concept (cf. Sontag and Wang 1995) is as uniform global asymptotic stability of the origin with respect to all possible time-varying feedback laws Δ bounded by ρ : $|\Delta(t, x)| \leq \rho(|x|)$. In other words, the system

$$\dot{x} = f(x, \Delta(t, x))$$

(Fig. 5) is stable uniformly over all such perturbations Δ . In contrast to the ISS definition, which deals with all possible “open-loop” inputs, the present notion of robust stability asks about all possible closed-loop interconnections. One may think of Δ as representing uncertainty in the dynamics of the original system, for example.

Theorem 4 (Sontag and Wang 1995) *A system is ISS if and only if it is robustly stable.*

Intuitively, the ISS estimate $|x(t)| \leq \max\{\beta(|x^0|, t), \gamma(\|u\|_\infty)\}$ says that the β term dominates as long as $|u(t)| \ll |x(t)|$ for all t , but $|u(t)| \ll |x(t)|$ amounts to $u(t) = d(t) \cdot \rho(|x(t)|)$ with an appropriate function ρ . This is an instance of a “small-gain” argument; see below.

Input-to-State Stability, Fig. 5 Margin of robustness

One analog for linear systems is as follows: if A is a Hurwitz matrix, then $A + Q$ is also Hurwitz, for all small enough perturbations Q ; note that when Q is a nonsingular matrix, $|Qx|$ is a $\mathcal{K}_\infty$ function of $|x|$.

Dissipation

Another characterization of ISS is as a dissipation notion stated in terms of a Lyapunov-like function. A continuous function $V : \mathbb{R}^n \rightarrow \mathbb{R}$ is said to be a *storage function* if it is positive definite, that is, $V(0) = 0$ and $V(x) > 0$ for $x \neq 0$, and proper, that is, $V(x) \rightarrow \infty$ as $|x| \rightarrow \infty$. This last property is equivalent to the requirement that the sets $V^{-1}([0, A])$ should be compact subsets of $\mathbb{R}^n$, for each $A > 0$, and in the engineering literature, it is usual to call such functions *radially unbounded*. It is an easy exercise to show that $V : \mathbb{R}^n \rightarrow \mathbb{R}$ is a storage function if and only if there exist $\underline{\alpha}, \bar{\alpha} \in \mathcal{K}_\infty$ such that

$$\underline{\alpha}(|x|) \leq V(x) \leq \bar{\alpha}(|x|) \quad \forall x \in \mathbb{R}^n$$

(the lower bound amounts to properness and $V(x) > 0$ for $x \neq 0$, while the upper bound guarantees $V(0) = 0$). For convenience, $\dot{V} : \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}$ is the function:

$$\dot{V}(x, u) := \nabla V(x) \cdot f(x, u)$$

which provides, when evaluated at $(x(t), u(t))$, the derivative $dV(x(t))/dt$ along solutions of $\dot{x} = f(x, u)$.

An *ISS-Lyapunov function* for $\dot{x} = f(x, u)$ is by definition a smooth storage function V for which there exist functions $\gamma, \alpha \in \mathcal{K}_\infty$ so that

$$\dot{V}(x, u) \leq -\alpha(|x|) + \gamma(|u|) \quad \forall x, u. \quad (\text{L-ISS})$$

Integrating, an equivalent statement is that, along all trajectories of the system, there holds the following dissipation inequality:

$$V(x(t_2)) - V(x(t_1)) \leq \int_{t_1}^{t_2} w(u(s), x(s)) ds$$

where, using the terminology of Willems (1976), the “supply” function is $w(u, x) = \gamma(|u|) - \alpha(|x|)$. For systems with no inputs, an ISS-Lyapunov function is precisely the same object as a Lyapunov function in the usual sense.

Theorem 5 (Sontag and Wang 1995) *A system is ISS if and only if it admits a smooth ISS-Lyapunov function.*

Since $-\alpha(|x|) \leq -\alpha(\bar{\alpha}^{-1}(V(x)))$, the ISS-Lyapunov condition can be restated as

$$\dot{V}(x, u) \leq -\tilde{\alpha}(V(x)) + \gamma(|u|) \quad \forall x, u$$

for some $\tilde{\alpha} \in \mathcal{K}_\infty$. In fact, one may strengthen this a bit (Praly and Wang 1996): for any ISS system, there is always a smooth ISS-Lyapunov function satisfying the “exponential” estimate $\dot{V}(x, u) \leq -V(x) + \gamma(|u|)$.

The sufficiency of the ISS-Lyapunov condition is easy to show and was already in the original paper (Sontag 1989). A sketch of proof is as follows, assuming for simplicity a dissipation estimate in the form $\dot{V}(x, u) \leq -\alpha(V(x)) + \gamma(|u|)$. Given any x and u , either $\alpha(V(x)) \leq 2\gamma(|u|)$ or $\dot{V} \leq -\alpha(V)/2$. From here, one deduces by a comparison theorem that, along all solutions,

$$V(x(t)) \leq \max \left\{ \beta(V(x^0), t), \alpha^{-1}(2\gamma(\|u\|_\infty)) \right\},$$

where the $\mathcal{KL}$ function $\beta(s, t)$ is the solution $y(t)$ of the initial value problem

$$\dot{y} = -\frac{1}{2}\alpha(y) + \gamma(u), \quad y(0) = s.$$

Finally, an ISS estimate is obtained from $V(x^0) \leq \bar{\alpha}(x^0)$.

The proof of the converse part of the theorem is based upon first showing that ISS implies robust stability in the sense already discussed and then obtaining a converse Lyapunov theorem for robust stability for the system $\dot{x} = f(x, d\rho(|x|)) = g(x, d)$, which is asymptotically stable uniformly on all Lebesgue-measurable functions $d(\cdot) : \mathbb{R}_{\geq 0} \rightarrow B(0, 1)$. This last theorem was given in Lin et al. (1996) and is basically a theorem on Lyapunov functions for

differential inclusions. The classical result of Massera (1956) for differential equations (with no inputs) becomes a special case.

Using “Energy” Estimates Instead of Amplitudes

In linear control theory, H_∞ theory studies $L^2 \rightarrow L^2$ induced norms, which under coordinate changes leads to the following type of estimate:

$$\int_0^t \alpha(|x(s)|) ds \leq \alpha_0(|x^0|) + \int_0^t \gamma(|u(s)|) ds$$

along all solutions, and for some $\alpha, \alpha_0, \gamma \in \mathcal{K}_\infty$. Just for the statement of the next result, a system is said to *satisfy an integral-integral estimate* if for every initial state x^0 and input u , the solution $x(t, x^0, u)$ is defined for all $t > 0$ and an estimate as above holds. (In contrast to ISS, this definition explicitly demands that $t_{\max} = \infty$.)

Theorem 6 (Sontag 1998) *A system is ISS if and only if it satisfies an integral-integral estimate.*

This theorem is quite easy to prove, in view of previous results. A sketch of proof is as follows. If the system is ISS, then there is an ISS-Lyapunov function satisfying $\dot{V}(x, u) \leq -V(x) + \gamma(|u|)$, so, integrating along any solution:

$$\begin{aligned} \int_0^t V(x(s)) ds &\leq \int_0^t V(x(s)) ds + V(x(t)) \\ &\leq V(x(0)) + \int_0^t \gamma(|u(s)|) ds \end{aligned}$$

and thus an integral-integral estimate holds. Conversely, if such an estimate holds, one can prove that $\dot{x} = f(x, 0)$ is stable and that an asymptotic gain exists.

Integral Input-to-State Stability

A concept of nonlinear stability that is truly distinct from ISS arises when considering a mixed notion which combines the “energy” of the input with the amplitude of the state. A system is said to be *integral input to state stable (iISS)* provided

that there exist $\alpha, \gamma \in \mathcal{K}_\infty$, and $\beta \in \mathcal{KL}$ such that the estimate

$$\begin{aligned} \alpha(|x(t)|) &\leq \beta(|x^0|, t) \\ &+ \int_0^t \gamma(|u(s)|) ds \quad (\text{iISS}) \end{aligned}$$

holds along all solutions. Just as with ISS, one could state this property merely for all times $t \in t_{\max}(x^0, u)$. Since the right-hand side is bounded on each interval $[0, t]$ (because, recall, inputs are by definition assumed to be bounded on each finite interval), it is automatically true that $t_{\max}(x^0, u) = +\infty$ if such an estimate holds along maximal solutions. So forward completeness (solution exists for all $t > 0$) can be assumed with no loss of generality.

One might also consider the following type of “weak integral to integral” mixed estimate:

$$\begin{aligned} \int_0^t \underline{\alpha}(|x(s)|) ds &\leq \kappa(|x^0|) \\ &+ \alpha \left(\int_0^t \gamma(|u(s)|) ds \right) \end{aligned}$$

for appropriate $\mathcal{K}_\infty$ functions (note the additional “ α ”).

Theorem 7 (Angeli et al. 2000) *A system satisfies a weak integral to integral estimate if and only if it is iISS.*

Another interesting variant is found when considering mixed *integral/supremum* estimates:

$$\begin{aligned} \underline{\alpha}(|x(t)|) &\leq \beta(|x^0|, t) \\ &+ \int_0^t \gamma_1(|u(s)|) ds + \gamma_2(\|u\|_\infty) \end{aligned}$$

for suitable $\beta \in \mathcal{KL}$ and $\underline{\alpha}, \gamma_i \in \mathcal{K}_\infty$. One then has:

Theorem 8 (Angeli et al. 2000) *A system satisfies a mixed estimate if and only if it is iISS.*

Dissipation Characterization of iISS

A smooth storage function V is an *iISS-Lyapunov function* for the system $\dot{x} = f(x, u)$ if there are a $\gamma \in \mathcal{K}_\infty$ and an $\alpha : [0, +\infty) \rightarrow [0, +\infty)$

which is merely *positive definite* (i.e., $\alpha(0) = 0$ and $\alpha(r) > 0$ for $r > 0$) such that the inequality:

$$\dot{V}(x, u) \leq -\alpha(|x|) + \gamma(|u|) \quad (\text{L-iISS})$$

holds for all $(x, u) \in \mathbb{R}^n \times \mathbb{R}^m$. To compare, recall that an ISS-Lyapunov function is required to satisfy an estimate of the same form but where α is required to be of class $\mathcal{K}_\infty$; since every $\mathcal{K}_\infty$ function is positive definite, an ISS-Lyapunov function is also an iISS-Lyapunov function.

Theorem 9 (Angeli et al. 2000) *A system is iISS if and only if it admits a smooth iISS-Lyapunov function.*

Since an ISS-Lyapunov function is also an iISS one, ISS implies iISS. However, iISS is a strictly weaker property than ISS, because α may be bounded in the iISS-Lyapunov estimate, which means that V may increase, and the state become unbounded, even under bounded inputs, so long as $\gamma(|u(t)|)$ is larger than the range of α . This is also clear from the iISS definition, since a constant input with $|u(t)| = r$ results in a term in the right-hand side that grows like rt .

An interesting general class of examples is given by *bilinear* systems

$$\dot{x} = \left(A + \sum_{i=1}^m u_i A_i \right) x + Bu$$

for which the matrix A is Hurwitz. Such systems are always iISS (see Sontag 1998), but they are not in general ISS. For instance, in the case when $B = 0$, boundedness of trajectories for all constant inputs already implies that $A + \sum_{i=1}^m u_i A_i$ must have all eigenvalues with nonpositive real part, for all $u \in \mathbb{R}^m$, which is a condition involving the matrices A_i (e.g., $\dot{x} = -x + ux$ is iISS but it is not ISS).

The notion of iISS is useful in situations where an appropriate notion of detectability can be verified using LaSalle-type arguments. There follow two examples of theorems along these lines.

Theorem 10 (Angeli et al. 2000) *A system is iISS if and only if it is 0-GAS and there is a smooth storage function V such that, for some*

$\sigma \in \mathcal{K}_\infty$:

$$\dot{V}(x, u) \leq \sigma(|u|)$$

for all (x, u) .

The sufficiency part of this result follows from the observation that the 0-GAS property by itself already implies the existence of a smooth and positive definite, but not necessarily proper, function V_0 such that $\dot{V}_0 \leq \gamma_0(|u|) - \alpha_0(|x|)$ for all (x, u) , for some $\gamma_0 \in \mathcal{K}_\infty$ and positive definite α_0 (if V_0 were proper, then it would be an iISS-Lyapunov function). Now one uses $V_0 + V$ as an iISS-Lyapunov function (V provides properness).

Theorem 11 (Angeli et al. 2000) *A system is iISS if and only if there exists an output function $y = h(x)$ (continuous and with $h(0) = 0$) which provides zero detectability ($u \equiv 0$ and $y \equiv 0 \Rightarrow x(t) \rightarrow 0$) and dissipativity in the following sense: there exists a storage function V and $\sigma \in \mathcal{K}_\infty$, α positive definite, so that:*

$$\dot{V}(x, u) \leq \sigma(|u|) - \alpha(h(x))$$

holds for all (x, u) .

The paper Angeli et al. (2000) contains several additional characterizations of iISS.

Superposition Principles for iISS

There are also asymptotic gain characterizations for iISS. A system is *bounded energy weakly converging state (BEWCS)* if there exists some $\sigma \in \mathcal{K}_\infty$ so that the following implication holds:

$$\begin{aligned} \int_0^{+\infty} \sigma(|u(s)|) ds < +\infty \\ \Rightarrow \liminf_{t \rightarrow +\infty} |x(t, x^0, u)| = 0 \quad (\text{BEWCS}) \end{aligned}$$

(more precisely, if the integral is finite, then $t_{\max}(x^0, u) = +\infty$, and the liminf is zero). It is *bounded energy frequently bounded state (BEFBS)* if there exists some $\sigma \in \mathcal{K}_\infty$ so that the following implication holds:

$$\begin{aligned} \int_0^{+\infty} \sigma(|u(s)|) ds < +\infty \\ \Rightarrow \liminf_{t \rightarrow +\infty} |x(t, x^0, u)| < +\infty \quad (\text{BEFBS}) \end{aligned}$$

(again, meaning that $t_{\max}(x^0, u) = +\infty$ and the $\liminf$ is finite).

Theorem 12 (Angeli et al. 2004) *The following three properties are equivalent for any given system $\dot{x} = f(x, u)$:*

- *The system is iISS.*
- *The system is BEWCS and zero stable.*
- *The system is BEFBS and zero GAS.*

Summary, Extensions, and Future Directions

This entry focuses on stability notions relative to steady states, but a more general theory is also possible, that allows consideration of more arbitrary attractors, as well as robust and/or adaptive concepts. Much else has been omitted from this entry. Most importantly, one of the key results is the *ISS small-gain theorem* due to Jiang, Teel, and Praly (Jiang et al. 1994), which provides a powerful sufficient condition for the interconnection of ISS systems being itself ISS. The extension of ISS to PDEs, especially to PDEs with inputs entering the boundary conditions, long remained elusive because of the need to consider unbounded input operators. However, ISS theory is now well-established for both parabolic and hyperbolic PDEs (Karafyllis and Krstić 2019), including stability results, obtained via small-gain arguments, for interconnections or parabolic and/or hyperbolic systems, in various physically meaningful norms.

Other topics not treated include, among many others, all notions involving outputs; ISS properties of time-varying (and in particular periodic) systems; ISS for discrete-time systems; questions of sampling, relating ISS properties of continuous and discrete-time systems; ISS with respect to a closed subset K ; stochastic ISS; applications to tracking, vehicle formations (“leader to followers” stability); and averaging of ISS systems. The paper Sontag (2006) may also be consulted for further references, a detailed development of some of these ideas, and citations to the literature for others. In addition, the textbooks Isidori (1999), Krstić et al. (1995), Khalil (1996), Sepul-

chre et al. (1997), Krstić and Deng (1998), Freeman and Kokotović (1996), Isidori et al. (2003) contain many extensions of the theory as well as applications.

Abstract

This chapter reviews the challenges for the extension of the Input-to-State Stability (ISS) property for systems described by Partial Differential Equations (PDEs). The methodologies that have been used in the literature for the derivation of ISS estimates, are presented. Examples are also provided and possible directions of future research on ISS for PDEs are given.

Keywords

Input-to-State Stability · Partial Differential Equations · Infinite-Dimensional Systems

Introduction

Input-to-State Stability (ISS) is a stability notion that has played a key role in the development

of modern control theory. ISS combines internal and external stability notions and has been heavily used in the finite-dimensional case for the stability analysis of control systems as well as for the construction of feedback stabilizers. The present chapter is devoted to the extension of the ISS property to infinite-dimensional systems and more specifically, to control systems that involve Partial Differential Equations (PDEs).

Problems and Methods for ISS for PDEs

The extension of input-to-state stability (ISS) to systems described by partial differential equations (PDEs) is a challenging topic that has required extensive research efforts by many researchers. The main reason for the difficulty of such an extension is the fact that there are key features which are absent in finite-dimensional systems but play an important role for the study of ISS in PDE systems. Such key features are:

- (1) The nature of the disturbance inputs. There are two cases for PDE systems where a disturbance input may appear: a disturbance may appear in the PDE itself (distributed disturbance) and/or in the boundary conditions (boundary disturbance). The transformation of a boundary disturbance to a distributed disturbance does not solve the problem because in this way time derivatives of the disturbance appear in the PDE. This happens because the boundary input operator is unbounded. This is a fundamental obstacle which cannot be avoided.
- (2) Systems described by PDEs require various mathematical tools. For example, the mathematical theory and techniques for parabolic PDEs are completely different from the mathematical theory and techniques for hyperbolic PDEs. Moreover, there are PDEs which may not fall into one of these two categories (hyperbolic and parabolic).
- (3) When nonlinear PDEs are studied, the place where the nonlinearity appears is very impor-

tant. PDEs with nonlinear differential operators are much more demanding than PDEs with linear differential operators and nonlinear reaction terms (semilinear PDEs).

- (4) A variety of spatial norms may be used for the solution of a PDE. However, the ISS property written in different state norms has a different meaning. For example, the ISS property in certain L^p norm with $p < +\infty$ cannot give pointwise estimates of the solution. On the other hand, the ISS property in the sup spatial norm can indeed give pointwise estimates of the state.
- (5) Different notions of a solution are used in the theory of PDEs. The notion of the solution of a PDE has a tremendous effect on the selection of the state space and the set of allowable disturbance inputs. So, if weak solutions are used for a PDE, then the state space is usually an L^p space with $p < +\infty$, and it makes no sense to talk about the ISS property in the sup norm. However, it should be noticed that the state space does not necessarily determine the (spatial) norm in the ISS property: for example, if the state space is $H^1(0, 1)$, then the ISS property may be written in an $L^p(0, 1)$ norm with $p \leq +\infty$.
- (6) While the main tool of proving the ISS property for finite-dimensional systems is the ISS Lyapunov function, there are important cases for PDEs where ISS Lyapunov functionals are not available (e.g., the heat equation with boundary disturbances and Dirichlet boundary conditions).
- (7) A PDE may or may not include nonlocal terms. Moreover, the nonlocal terms may appear in the boundary conditions of a PDE system. The latter case is particularly important for control theory, because it is exactly the case that appears when boundary feedback control is applied to a PDE system. However, it should be noticed that PDEs with nonlocal terms are not always covered by standard results of the theory of PDEs.

All the above features do not appear in systems described by ordinary differential equations (ODEs), and this has led the research community

to create novel mathematical tools which can be used for the derivation of an ISS estimate for the solution of a PDE. So far research has mostly focused on 1-D linear or semilinear PDEs. The reader can consult the recent book (Karafyllis and Krstic 2019b) for a detailed description. More specifically, for hyperbolic PDEs researchers have used:

- (a) ISS Lyapunov functionals, which usually provide ISS estimates in L^p norms with $p < +\infty$, and
- (b) the strong relation between hyperbolic PDEs and delay equations (see Bekiaris-Liberis and Krstic (2013) and Karafyllis and Krstic 2014, 2017b). This relation is most useful in 1-D hyperbolic PDEs and provides ISS estimates in the sup spatial norm.

For parabolic PDEs researchers have used numerically inspired methods which relate the solution of a PDE to the solution of a finite-dimensional discrete-time system. Such methods were used in Karafyllis and Krstic (2017a, 2019b), where ISS estimates in various spatial state norms were derived (including the sup spatial norm). Researchers have also used:

- (a) ISS Lyapunov functionals,
- (b) Eigenfunction expansions of the solution, which can be used for the L^2 spatial norm as well as for the spatial H^1 norm,
- (c) Semigroup theory, which is particularly useful for linear PDEs, and
- (d) Monotonicity methods, i.e., methods that exploit the monotonicity of a particular PDE system (see Mironchenko et al. 2019).

Examples of Results of ISS for PDEs

As an example, consider the 1-D heat equation

$$\frac{\partial u}{\partial t}(t, x) = p \frac{\partial^2 u}{\partial x^2}(t, x) + f(t, x),$$

for all $(t, x) \in (0, +\infty) \times (0, 1)$ (1)

where $p > 0$ is a constant, subject to the boundary conditions:

$$u(t, 0) - d_0(t) = u(t, 1) = 0 \quad (2)$$

where $d_0 : \mathfrak{R}_+ \rightarrow \mathfrak{R}$ is a given locally bounded boundary disturbance input and $f : \mathfrak{R}_+ \times [0, 1] \rightarrow \mathfrak{R}$ is a locally bounded distributed input. Using the results in Chapter 5 and Chapter 6 of Karafyllis and Krstic (2019a), we have that:

- every solution $u \in C^0(\mathfrak{R}_+; L^2(0, 1))$ with $u \in C^1((0, +\infty) \times [0, 1])$ satisfying $u[t] \in C^2([0, 1])$, (2) for $t > 0$ and (1) satisfies the following ISS estimate for all $t > 0$

$$\begin{aligned} \|u[t]\|_2 &\leq \exp\left(-p\pi^2 t\right) \|u[0]\|_2 \\ &\quad + \frac{1}{\sqrt{3}} \sup_{0 < s < t} (|d_0(s)|) \\ &\quad + \frac{1}{p\pi^2} \sup_{0 < s < t} (\|f[s]\|_2) \end{aligned} \quad (3)$$

- every solution $u \in C^0(\mathfrak{R}_+ \times [0, 1])$ with $u \in C^1((0, +\infty) \times [0, 1])$ satisfying $u[t] \in C^2([0, 1])$ for $t > 0$, $u[0] \in H^2(0, 1)$, (2) for $t \geq 0$ and (1) satisfies the following ISS estimate for all $t \geq 0$

$$\begin{aligned} \|u[t]\|_\infty &\leq \sqrt{2} \max \\ &\quad \times \left(\exp\left(-\frac{p\pi^2}{4} t\right) \|u[0]\|_\infty, \right. \\ &\quad \left. \sup_{0 \leq s \leq t} (|d_0(s)|) \right) \\ &\quad + \frac{4\sqrt{2}}{p\pi^2} \sup_{0 \leq s \leq t} (\|f[s]\|_\infty) \end{aligned} \quad (4)$$

where $\|u[t]\|_2 = \left(\int_0^1 u^2(t, x) dx \right)^{1/2}$ and $\|u[t]\|_\infty = \max \{ |u(t, x)| : x \in [0, 1] \}$. The reader can notice the difference between estimates (3), (4). As remarked above the selection of different spatial (state) norms leads to completely different ISS estimates.

Small-gain results are also useful for the derivation of ISS estimates for various kinds of PDE systems. In the book Karafyllis and Krstic (2019a), small-gain methods were used for the study of ISS in a wide variety of PDE loops (i.e., interconnected PDEs). Moreover, PDE-ODE loops were also studied. It should be noticed that small-gain results rely on accurate estimations of the gain functions (or gain coefficients), and consequently, it is usually the case that small-gain results cannot be used in conjunction with qualitative characterizations of the ISS property.

Summary and Future Directions

The effort for a complete qualitative characterization of ISS for PDEs continues; the reader should consult (Mironchenko 2016) and notice that many characterizations of the ISS property for ODEs are not valid for PDEs. It should be also noted that at this point in time, there has been very little research devoted to the Input-to-Output Stability (IOS) property.

It is expected that ISS theory for PDEs will enable researchers to solve important feedback design problems and observer design problems. ISS was recently used in Karafyllis and Krstic (2019b) for boundary feedback design in 1-D parabolic semilinear PDEs with nonlinear reaction terms that satisfy a linear growth condition. Future research may address feedback stabilization problems for systems of PDEs as well as more complicated mathematical models, such as free-boundary parabolic PDEs. The ISS property for a boundary controlled Stefan problem was recently shown in Koga (2018). Since PDEs are used for the mathematical modeling of many phenomena, it is also expected that ISS theory for PDEs will have important applications to all sciences.

Interaction Patterns as Units of Analysis in Hierarchical Human-in-the-Loop Control

Department of Aerospace Engineering and
Mechanics, University of Minnesota,
Minneapolis, MN, USA

Abstract

Interaction patterns (IPs) are coordinated, sensory-motor behaviors used by human operators to effectively interact with complex task environments. They take different forms depending on the domain of activity. In spatial control tasks, IPs take the form of guidance

primitives that connect discrete environment features with the continuous control and guidance behavior. In particular they can be used to explain the emergence of subgoals and the partitioning of a spatial control problem's workspace.

IPs are significant also because they explain the functional integration of sensory, perceptual, guidance, and control processes. They also represent a keystone in the formation of hierarchical control strategies, where they provide an interface between the low-level sensory and control functions and the high-level cognitive functions. Finally – and more generally – they provide a critical insight into the acquisition of human operators' higher-level control functions.

Meta control · Sensory-motor patterns ·
Motion primitives · Perception

Introduction

Motivation

Machines have been climbing the ladder of human skills, and as a result, human operators are expected to interact with machines, at both a higher level and across a more comprehensive control hierarchy. This has been the trend in process control, and it is now underway in spatial control applications, as is already manifest in various autonomous guidance and robotic applications.

The acquisition of skills for complex tasks depends on the ability to form abstractions, including meta control such as motion primitives (see so-called options in reinforcement learning (Sutton et al. 1998)). In general, these are not just simple control abstractions or concatenations of inputs, but correspond to comprehensive input-output patterns associated with agent-environment dynamics. These sensory-motor patterns are critical for enabling more effective interactions with the task and environment elements.

Human control has been primarily investigated at the low-level control functions, such

as tracking and stabilization (see, e.g., McRuer and Krendel 1974). One of the most influential hierarchical control frameworks in human systems modeling and design is Rasmussen's model of human information processing and performance Rasmussen (1983). The framework delineates performance according to skills, rules, and knowledge (signals, signs, and symbols). However, the delineation between levels of processing has not been formally researched in complex tasks which rely on adaptive, agile behaviors. Hierarchical frameworks for such systems are challenging to formalize because they require deeper understanding of the integration between sensing, control, guidance, and planning functions.

Linking the symbolic and signal domains requires an interface that doesn't impose artificial constraints on the system and behavior. Consider the example in Fig. 1, which shows the workspace of a relatively simple navigation problem. A human or artificial agent with dynamics $\dot{\mathbf{x}} = f(\mathbf{x}, \mathbf{u})$ (where $\mathbf{x} \in \mathcal{X} \subseteq \mathbb{R}^n$ is the state of the agent and $\mathbf{u} \in \mathcal{U} \subseteq \mathbb{R}^m$ is the control) has to reach the goal x_g from a starting location x_0 while avoiding the obstacles O_1 and O_2 . In such navigation and guidance problems, waypoint-based algorithms provide useful abstractions; however, many such algorithms define waypoints top-down, for example, using geometrical heuristics that don't account for the dynamic interactions with the environment as illustrated in Fig. 1.

As illustrated in Fig. 1, it is possible to define a type of guidance primitive that describes the behavior through subgoals g_i leading to the goal. These types of abstractions have been identified in human guidance experiments (Kong and Mettler 2013) and have been shown to be related to patterns in the human guidance behavior, emerging from the closed-loop dynamics combining the effect of the environment on the dynamic response and, reciprocally, the effect of the dynamics on the agent's environment. Therefore, they have been called interaction patterns (IPs).

In the most general sense, IPs are patterns in the dynamics of the agent's interactions with the environment. IPs result from several factors,

Interaction Patterns as Units of Analysis in Hierarchical Human-in-the-Loop Control, Fig. 1 Toy navigation problem example highlighting interaction patterns $\pi_1, \pi_2, \dots$ acquired by the operator to effectively navigate through the environment. The figure also shows how these patterns delineate the behavior and define subgoals $g_1, g_2, \dots$ that can be used to abstract the dynamic behavior. The gaze vector r_{gaze} is added to underscore that the behavior results from a perception-action process used to support the interaction with the environment

including guidance skills that build on the natural agent-environment dynamics and, at the same time, planning skills that can exploit the larger patterns. The relationship between the agent dynamics and control and the structure of the larger behavior explains why understanding appropriate units of analysis for complex skills has been elusive. IPs, like patterns in other domains, are interesting because the regularities in the local behavior, as well as the larger organization and structure they confer, can be used to understand unobservable processes and principles related to human skills (Mumford and Desolneux 2010).

For example, IPs illustrate that there are units of organization beyond the basic trajectories and that these have to be considered in other human in the loop control applications. Such units are relevant in many applications because they result in a hierarchical description of behavior. As illustrated in Fig. 2, IPs link the domain of physical implementation, which is dictated by agent dynamics (including the effects of low-level

Interaction Patterns as Units of Analysis in Hierarchical Human-in-the-Loop Control, Fig. 2 Functional hierarchical model based on the IPs and the subgoal

abstraction. Notice the role of the IPs as the interface between low-level and the high-level control, i.e., cognitive control

control and sensing), with the abstract domain of reasoning and planning (Mettler et al. 2015). To summarize, finding control abstractions and what may be considered appropriate units of behavior that are derived from natural properties of the application domain represents one of the central problems for understanding higher-level skills such as learning, knowledge transfer, and

adaptation. These units of behavior also play a critical role in the system-wide organization of processes such as for hierarchical modeling. The following provides general background and summarizes the system-level foundations needed to understand and analyze such patterns. The entry also describes the larger significance for hierarchical modeling of human-in-the-loop control.

Background

Units of Behavior

A strategy to overcome human information processing limitations is chunking, which is the process of collecting multiple pieces of information under a single unit. This concept has primarily been studied in the domain of perception and memory (see, e.g., the early work on perceptual chunking in chess (Chase and Simon 1973)). In engineering and computer sciences, motion primitives (MPs) have been popular abstractions of dynamics. For example, in Frazzoli et al. (2002), MPs are formulated as quantization of the dynamics, i.e., they approximate the trajectories of the nonlinear dynamics through a set of equilibrium trajectories and a set of maneuvers needed to transition between the former. MPs emphasize the control – or output side of the performance – but neglect the input side and larger environment interactions. Motion primitives have also been proposed and studied in neurosciences, in particular motor control (see Flash and Hochner (2005) for a review).

In spatial control domains, chunking implies some form of coordination mechanisms combining sensory stimuli and control, leading to some behavior patterns that are useful for the task performance. From a behavioral standpoint, these patterns are a form of functional unit supporting key interactions with the environment, such as circumventing the obstacles in Fig. 1.

From a systems perspective, units of behavior must satisfy the constraints of the hierarchical system. As depicted in Fig. 2, the behavioral chunks have to provide an interface between low-level and high-level control and higher-level planning (and attention), therefore linking the continuous and discrete elements of behavior delineated in Rasmussen's model.

The concept of IPs thus generalizes that of MPs by incorporating inputs and the environment interaction. And, as can be seen above, IPs can be seen as a chunking approach for spatial control systems that also help elucidate the hierarchical system organization.

Organizational Units and Invariants

A central question is what principles govern the formation of IPs and the larger behavior organization such as shown in Fig. 1. It is expected that agents or human operators can exploit a range of invariants in how they sense and respond to situations and how they coordinate behavior. The following considers two types of invariants: the first are properties of trajectories that remain invariant to transformations, and the other are more general properties of trajectories that are invariant with respect to equivalence relations (see below).

In motion guidance, Tau theory has been validated in many perceptual guidance tasks (Lee 1998). Tau theory stipulates that an agent uses invariants in the perceptual field to sense and regulate the time-to-closure between the desired and current state (motion gap). Behaviors resulting from tau guidance produce perception-action patterns. Patterns from Tau guidance, or similar guidance laws, therefore can be viewed as a form of sensory-motor chunks (Mettler et al. 2015, 2017). However, there has been little research on their role in the macroscopic organization of behavior and larger control hierarchy.

It is well established that human problem-solving in general exploits invariants in the problem domain (Simon 1990). The intuition about abstractions and subgoals such as in Fig. 1 is that, while the specific tasks and their environments may be different, the subtasks are generally transferable between different tasks within the same problem domain. Therefore, these subtasks must satisfy invariant properties. The invariants are expected to be specific to the larger task or problem domain and not the specific problem, which explains why skills can transfer within similar domains. In spatial control, several invariants are available to the agents as described next using a systems formulation.

Agent-Environment Systems Formulation

To characterize the principles that help explain the formation of spatial control abstractions, the

first step is to formulate an agent-environment system (for details see Kong and Mettler 2013 and Mettler et al. 2015).

Dynamic Systems and Agent-Environment Dynamics

In traditional control applications, spatial control is often formulated as a trajectory generation problem. The main problem elements (see Fig. 1) include the vehicle dynamics with state-space domain $\mathcal{X} \subset \mathbb{R}^n$, evolving in a workspace $\mathcal{W} = \mathcal{O}_E \cup \mathcal{F}$, consisting of free space ($\mathcal{F}$) and obstacles ($\mathcal{O}_E = \bigcup_{i=1}^k \mathcal{O}_i$). The closed-loop agent-environment dynamics emphasize the effects of coupling between the agent and the environment mediated by the control sensing functions. They are given as:

$$\dot{\mathbf{x}} = f(\mathbf{x}, k(\mathbf{x}, h(g(\mathbf{x}))))). \quad (1)$$

Please refer to Fig. 2 for the definition of the symbols, and note that letter g is also used to designate subgoals.

Guidance Behavior and Interaction Patterns

The *guidance behavior* is defined as the collection of closed-loop state trajectories, $\mathbf{x}^u(t; \mathbf{x}_0)$, together with the corresponding environment state trajectories, $\mathbf{e}(t) = g(\mathbf{x}(t))$, resulting from the closed-loop dynamics (Eq. 1). The combination of state, input, and environment defines the extended state space $\tilde{\mathcal{X}} = \mathcal{X} \times \mathcal{U} \times \mathcal{E}$, which represents the domain of valid guidance behaviors.

Closed-loop interactions are typically produced by a combination of guidance and planning processes (see Fig. 2). Given additional constraints on their operation, the combination of processes results in guidance behavior forming patterns $\pi_i \in \tilde{\mathcal{X}}$ organized around subgoals g_i such as π_1, π_2, π_3 in Fig. 1.

IPs π_i are the sets of trajectories associated with a guidance and planning process. Referring to these patterns as interaction patterns (IPs) emphasizes that they arise from emergent closed-loop interactions of the agent-environment system (Fig. 2). The patterns can be delineated

into different subsets based on their characteristics, forming a library $\Pi := \{\pi_1, \pi_2, \dots\}$. The general idea, illustrated by Fig. 2, is that the IPs should provide structural features that can be exploited by the high-level perception and planning functions. For example, IPs identified in Kong and Mettler (2013) have provided evidence for operators' exploiting invariants in the closed-loop agent-environment dynamics.

Interaction Patterns and Invariant Properties

Invariants are significant because they represent one way of exploiting structural characteristics in the behavior (Eq. 1). Invariants can be captured through equivalence relations. An equivalence relation $\sim_e$ is a binary relation between elements of a set, in this case, the set of trajectory segments $s \in \Pi$. Two types of equivalence relation were defined in Kong and Mettler (2013) following the properties found in human guidance behavior.

First, guidance laws are generally invariant to rigid-body translation and rotation transformations, which is similar to the invariants underlying MPs, but a key difference here is that the invariant has to be extended to environment trajectories $\mathbf{e}(t)$. This *first equivalence*, described by $\sim_g$ for group action equivalence, derives from the symmetry group M (group action $\Psi : M \times \mathcal{X} \rightarrow \mathcal{X}$).

Second, IPs describe coordinated motions relative to specific environment features, and since IPs break up the task into subtasks, they define subgoals. The trajectories within IPs, e.g., π_1 in Fig. 1, are related through their subgoal g_1 , i.e., once trajectories pass through the subgoal, they share the same trajectory. This relationship has been described by the so-called subgoal equivalence $\sim_s$.

Equivalence Relations and Behavior Organization

Behaviors segments s that satisfy some equivalence relationship $\sim_e$ define an equivalence class:

$$[s]_{\sim_e} = \{s_2 \in \tilde{\mathcal{X}} | s_1 \sim_e s_2\}. \quad (2)$$

Equivalence classes partition the state space $\tilde{\mathcal{X}}$, which explains their role in reducing representational complexity. For example, the IPs in Fig. 1 partition the problem space into distinct regions, which explains their role in the macroscopic organization and planning of spatial behavior.

Finally, with guidance that produces adequate IPs (satisfy the group and subgoal equivalences), the environment can be abstracted by the subgoals, and the agent-environment interactions can be simplified to a guidance behavior relative to subgoals. The set of all interaction patterns for an agent and its environment is called an *interaction pattern library*, which can be denoted Π , and enables a parsimonious representation of the extended state space $\tilde{\mathcal{X}}$:

$$\tilde{\mathcal{X}} \rightarrow \Pi := \{\pi_1, \pi_2, \dots\} \quad (3)$$

With this abstraction, the spatial behavior can be described and represented using the symbols belonging to Π .

Interaction Patterns and Systems Modeling

IPs are interesting from a system's perspective, because they combine functional and behavioral dimensions (Mettler et al. 2017). The functional properties arise from the IPs' grounding in the closed-loop perception and guidance mechanisms. As shown in Fig. 2, the IPs are produced by the guidance process and represent the basic behavioral elements leveraged by the planning and control hierarchy. They also make it possible to delineate the hierarchical control functions, their mechanisms, and associated information.

Functional Hierarchical Model Overview

Figure 3 elaborates these ideas using Rasmussen's three levels: symbol, cue, and signal. At the top level, the behavior is described by a sequence of IPs and corresponding subgoals relative to the environment elements and task objectives (Fig. 3a). This allows formalization of

Interaction Patterns as Units of Analysis in Hierarchical Human-in-the-Loop Control, Fig. 3 Illustration of the levels of operator's interactions for the spatial control task in Fig. 1. The levels are organized based on the functional hierarchical model, highlighting the parallels with Rasmussen's levels of information processing. The

bubbles indicate the mental models associated with the different levels of control. (a) Task-level perception and planning. (b) Subgoal activation. (c) Perceptual guidance (e.g., tau gap closure). (d) Low-level control (tracking and stabilization)

the task representation, which can, for example, be described using a subgoal graph (Verma and Mettler 2016). The plan is provided as a sequence of subgoals $g_1, g_2, \dots, x_g$. The perceptual function at this level is responsible for the identification of task elements and designation of subgoals (Fig. 3a).

At the intermediate level, the system component is conceptualized as the interaction pattern IP. The control actions correspond to the settings that configure the physical control/perceptual system to produce the desired agent-environment interaction (e.g., Tau or other guidance in Fig. 3c). The guidance process produces the trajectory needed to reach the active subgoal. The perceptual function at this level is responsible for extracting necessary cues (e.g., Tau motion gaps in Fig. 3b).

At the lowest level, the behavior is produced by a control process shaping the dynamic response needed to track the trajectory profiles provided by the guidance law (Fig. 3d). Typical models at this level include nonlinear feed-forward inverse controller, together with feedback control actions, which produce the control reference trajectories necessary to implement the behavior (control input u and reference y_{ref}) Mettler and Kong (2013).

Interaction Patterns in Applications

The IPs can be used in modeling and analysis of a range of spatial control applications for human-in-the-loop systems and artificial agents.

Modeling Applications

Specifically, the subgoal equivalence provides the basis for the decomposition of behavior into hierarchical elements. The decomposition proceeds according to the hierarchical model, starting with the subgoal equivalence, which enables segmentation according to the IPs. This “lawful” decomposition makes it possible to tear the behavior apart along functionally meaningful segments (see Mettler and Kong 2012). The dynamic behavior and trajectories associated with the identified IPs can subsequently be used to analyze and model the behavior, including:

1. Modeling the guidance and control mechanisms underlying the IPs π_i .
2. Modeling of the higher-level functions, including planning, visual attention, memory representation, and learning.

To illustrate this approach, Feit and Mettler (2016) provides an example of functional modeling of the control and perceptual processes of guidance primitives. The functional properties were captured using structure learning techniques (Bayesian graph). Subsequently, trajectories within control modes were used to identify perceptual and guidance mechanisms.

Verma and Mettler (2016) provides another example, here an investigation of learning task environments using IPs as the unit of behavior. Using the IPs for the analysis helps raise the level of analysis into visual attention and memory structure associated with the learning process.

Engineering Design Applications

In parallel to modeling and analysis, the hierarchical framework can be used to design and implement control augmentations in human-machine systems. The general idea of this work is that the hierarchical framework enables design of operator interactions based on the functional organization of the information processing. Tseng and Mettler (2016) demonstrates how IPs can be used to model human strategies in search applications with a tele-operated mobile robot. In this example, the subgoals are used as control abstractions to augment the operator (Tseng and Mettler 2020). In Andersh and Mettler (2018), the opposite strategy is applied, the human visual gaze inputs provide the high-level subgoal information, and an artificial low-level controller assists with the guidance and control processes.

Future Research and Applications

Modeling and analysis of humans’ hierarchical control architecture is critical to enabling more rigorous and comprehensive human skill analysis, as well as the design of natural and effective human-machine interfaces. The interaction patterns and functional hierarchical model provide a holistic, system-level understanding of behavior

in artificial and natural agents. The improved knowledge about the principles of hierarchical control is also critical for designing computationally efficient and versatile guidance algorithms for autonomous vehicles. In particular, the idea would be to continue leveraging concepts from ecological psychology, such as direct perception and the concept of affordances (Gibson 1977; Stoffregen 2003). This understanding can also be helpful for the elaboration of new design principles for machine vision, for example, by integrating the functions into complete units of operation, such as the coordination of perceptual and control dimensions leading to IPs.

Skill acquisition can be conceptualized as the problem of learning hierarchical control architecture. The hierarchical functional model can be used for human learning, skill analysis, and machine learning approaches. Hierarchical control, and more specifically, the definition of subgoals, has been central to more efficient reinforcement learning algorithms, including deep hierarchical learning. Many demonstrations, however, have so far focused on video games which don't replicate the complexity of natural environment interactions. Finally, the functional understanding enabled by a more detailed hierarchical model can be useful to formulate stronger hypotheses in cognitive neuroscience.

Interactive Environments and Software Tools for CACSD

Vasile Sima

National Institute for Research and Development
in Informatics, Bucharest, Romania

Abstract

The main functional and support facilities offered by interactive environments and tools for Computer-Aided Control System Design (CACSD) and reference examples of such software systems are presented, from both a user and a developer perspective. The essential functions these environments should possess and requirements which should be satisfied are discussed. The importance of reliability and efficiency is highlighted, besides the desired friendliness and flexibility of the user interface. Widely used environments and software tools for CACSD, including MATLAB, Mathematica, Maple, and the SLICOT Library, serve as illustrative examples.

Keywords

Automatic control · Controller design ·
Numerical algorithms · Simulation · User
interface

Introduction

The complexity of many processes or systems to be controlled and the strong performance requirements to be fulfilled nowadays make it very difficult or even impossible to design suitable control laws without resorting to dedicated software tools. Computer-Aided Control System Design (CACSD) is the use of computer programs to support the creation, analysis, evaluation, or optimization of a control system design. CACSD is a specialization of Computer-Aided Design (CAD) for control systems. CAD is used in many domains, to enhance designer's productivity and

the design quality and to manage the design versions and documentation.

The interactive environments and tools for CACSD have evolved significantly during the last decades, in parallel with the developments of numerical linear algebra, scientific computations, and computer hardware and software, including programming and networking capabilities. Starting from simple collections of specialized tools for solving well-defined system analysis and design problems, CACSD became increasingly more sophisticated and powerful, allowing complicated tasks to be orchestrated for fully covering the control engineering design, prototyping, testing, and deployment. Modelling, system analysis and synthesis, and control system assessment are activities which are assisted by the nowadays advanced CACSD environments and software tools. The main aim is to help the designer to concentrate on the design problem itself, not on theoretical approaches, numerical algorithms, and computational details. Moreover, CACSD environments allow the developers and users to do conceptual thinking but also programming and debugging at a higher level of abstraction, in comparison with standard programming languages, like Fortran, C/C++, or JavaTM.

There are both commercial or free and open-source CACSD environments and tools. State-of-the-art CACSD systems exist for several platforms (Windows, Linux/UNIX, and Mac OS X). Multiple high speed CPUs, graphics cards, and large amounts of RAM are well-suited to perform graphically and computationally intensive tasks. A common feature is the presence of a "friendly" graphical user interface, but often a dedicated command language is also available. The user interacts with the CACSD environment either by specifying the model or control structure, the design requirements, and the values of essential parameters or by selecting and combining the tools to be used. The process can be repeated until a satisfactory behavior is obtained.

Usually, the underlying computational tools, on which the interactive environments are based on, are hidden to the user. Moreover, software for extensive testing is not normally provided, but demonstrators running few examples are offered.

Unfortunately, even mathematically simple problems of small dimension can conduct to wrong results when using unsuitable algorithms. Illustrative control-related examples are given, e.g., in Van Huffel et al. (2004). Since system analysis and design tasks usually involve sequential or iterative solution of complex subproblems, it follows that the quality of the intermediate results is of utmost importance. Consequently, the interactive environments for CACSD should be based on reliable, efficient, and thoroughly tested computational building blocks, which are called at the lower layers of calculations. These blocks constitute the computational engine of an interactive environment.

Figure 1 gives a typical hierarchy of the software components incorporated in an interactive CACSD environment.

Interactive Environments and Software Tools

The interactive environments can be divided into general purpose numerical systems, such as MATLAB® from The MathWorks, Inc., Octave, Scilab, Julia, or OML, and computer algebra systems, such as Mathematica from Wolfram, or Maple from Waterloo Maple Inc. (Maplesoft).

The software tools for CACSD are also formally divided into computational and support tools. The SLICOT Library and Dymola serve as illustrative examples.

Main Functionality

A comprehensive set of functions of, and requirements for interactive environments for control engineering, is described in MacFarlane et al. (1989), but such a set has probably not yet been covered by any single environment. State-of-the-art interactive environments and software tools for CACSD include many attractive functional features:

- define or find (via first principles or system identification) various system models (e.g., state-space models or transfer-function matrices), and convert between different representations;
- find reduced order (or simplified) models, which can more economically be used for simulation, control, prediction, etc.;
- analyze basic system properties, like stability, controllability, observability, stabilizability, detectability, minimality, properness, etc.;
- analyze interactively the behavior of a control system for various scenarios;

Interactive CACSD environment (e.g., MATLAB, Mathematica, Maple) (for modelling, simulation, analysis, synthesis, etc.)
Toolboxes or packages with executables or functions written in the environment language
(Graphical) User interface, Interactive language, Graphical functions, API
CACSD subroutine libraries (e.g., SLICOT)
Mathematical subroutine libraries (e.g., LAPACK, ARPACK, IMSL, NAG)
Computer-optimized mathematical libraries or their generators (e.g., BLAS, MKL, ATLAS)
Libraries of intrinsic functions (e.g., in Fortran or C/C++)

Interactive Environments and Software Tools for CACSD, Fig. 1 Hierarchy of the software components incorporated in an interactive CACSD environment

- provide alternative tools for different categories of users, from novice to expert and from classical to “modern” or advanced analysis and synthesis techniques, in time domain or frequency domain;
- provide a wide range of tools, covering modelling, system identification, filtering, control system design, simulation, real-time behavior, hardware-in-the-loop simulation, and code generation for easy deployment; ensure their interoperability;
- allow the user to add extensions at various levels: new functions, interfaces, or even toolboxes or packages, which can be made available to a general community; allow customization.

In addition to the functional and computational tools, essential components of an interactive environment are the user interface, the application program interface (API), and the support tools, which enable to easily specify, document and store a design solution, visualize and interpret the results, export the results to other applications for further processing, generate reports, etc.

It is a common feature of interactive environments for CACSD to address the requirements of a large diversity of users, in various stages of familiarity with the environment. This feature is expressed, e.g., by the option to use either a graphical user interface or a command language to call and sequence various computational procedures. In addition, tools for easy building new computational or graphical procedures, or for managing the codes and results, are often included. The command language often operates both on low-level data constructs, such as a matrix, and on high-level ones (e.g., system objects) and allows operator overloading (e.g., taking $G_1 * G_2$ as the result of a series interconnection of the systems represented by G_1 and G_2).

An environment for CACSD should integrate advanced user interfaces and API, a collection of problem-solvers based on reliable and efficient numerical and possibly symbolic algorithms, and tools for visualizing and interpreting the results.

Widely used such environments are, for instance, MATLAB, Mathematica, or Maple, presented in the next subsection. There are also environments dedicated to modelling and simulation, which cover a broad range of technical and engineering computations, including those for mechanical, electrical, thermodynamic, hydraulic, pneumatic, or thermal systems. An example is Dymola, presented in a subsequent subsection, or COMSOL Multiphysics®.

Reference Interactive Environments

MATLAB (MATrix LABoratory) is an integrated, interactive environment for technical computing, visualization, and programming (MathWorks® 2013). Based on a powerful high-level interpreter language and development tools, an easy-to-use, flexible, and customizable graphical user interface, complemented with attractive visualization capabilities, and open for extensions with new toolkits, MATLAB can be used for solving intricate scientific and engineering problems, as well as for development and deployment of applications.

MATLAB® and Simulink® are registered trademarks of The MathWorks, Inc. MATLAB, Simulink, and several toolboxes, including System Identification Toolbox, Control System Toolbox, and Robust Control Toolbox, are suitable for solving various control engineering problems; other toolboxes, such as Signal Processing Toolbox, Optimization Toolbox, and Symbolic Math Toolbox, offer additional useful facilities. See <https://www.mathworks.com/products/>.

Simulink is a high-level implementation of the engineering approach, based on block diagrams, to analyze and design control systems. It is also a powerful modelling and multi-domain simulation and model-based design tool for dynamic systems, which supports hierarchical system-level design, simulation, automatic code generation, and continuous test and verification of embedded systems. Simulink offers a graphical editor, customizable block libraries, and solvers for modelling and simulation. The models may include MATLAB algorithms, and the simulation results may be further processed in MATLAB.

Managing projects (files, components, data), connecting to hardware for real-time testing, and deploying the designed system are additional, useful Simulink features. Real-Time Workshop code generation allows to speed up the design and implementation, by generating syntactically and semantically correct code which can be uploaded to the target machine. The capabilities for rapid prototyping are complemented by capabilities for developing and testing new mathematical or control theories and algorithms.

MATLAB offers support for object-oriented programming and interfacing with other languages, or connecting to similar environments. When using the command line interface, MATLAB helps the user, e.g., by showing the arguments of the typed MATLAB functions; also, it allows execution profiling, for increasing the computational efficiency, and its editor can suggest changes in the user M-functions for improving the performance. MATLAB users may upload their own contributions to the MATLAB Central website or may download tools developed by other people. User feedback is used by the MATLAB developers to improve its functionality, reliability, and efficiency.

Commercial competitors to MATLAB include Mathematica, Maple, and IDL; free open-source alternatives are, e.g., GNU Octave, FreeMat, and Scilab, intended to be mostly compatible with the MATLAB language. For instance, a set of free CACSD tools for GNU Octave version 3.6.0 or beyond has been recently developed (see <https://octave.sourceforge.io/control/>). The Octave extension package called *control* is based on the SLICOT Library and includes functionalities for system identification, system analysis, control system design (including H_∞ synthesis), and model reduction, which are the basic steps of the control engineer design workflow.

Mathematica is an interactive environment which supports complete computational workflows, making it suitable for a convenient endeavor from ideas to deployed solutions (see <https://www.wolfram.com/mathematica/>). Mathematica offers, e.g., tools for 2D and 3D data and function visualization and animation,

numeric and symbolic tools for discrete and continuous calculus, a toolkit for adding user interfaces to applications, control systems libraries, tools for parallel programming, etc. High-performance computing capabilities include the use of packed and sparse arrays, multi-precision arithmetic, automatic multi-threading on multicore computers (based on processor specific optimized libraries), hardware accelerators, support for grid technology, and CUDA and OpenCL GPU hardware. Mathematica and SystemModeler (based on Modelica[®] language) offer numerous built-in functions which allow to design, analyze, and simulate continuous- and discrete-time control systems, simplify models, interactively test controllers, and document the design. Both classical and modern techniques are provided. A powerful symbolic-numeric computation engine and highly efficient numerical algorithms are used. Mathematica allows to define the system models in a natural form. It can analyze not only numeric systems but also symbolic ones, represented by state-space or transfer-function models. The computational precision and algorithms can be automatically controlled and selected, respectively.

Maple is a computer algebra system, which combines a powerful engine for mathematical calculations with an intuitive user interface (see <https://www.maplesoft.com/>). Classical mathematical notation can be used, and the interface is customizable. Arbitrary precision numerical computations, as well as symbolic computations, can be performed. The Maple language is provided by a small kernel. NAG Numerical Libraries, ATLAS libraries, and other libraries written in this language are used for numerical calculations. Symbolic expressions are stored as directed acyclic graphs. Maple includes some CACSD tools for linear and nonlinear dynamic systems. For instance, the built-in package DynamicSystems (available since Maple 12 release) covers the analysis of linear time-invariant systems. Numerical solvers for Sylvester and Lyapunov equations have been added to the Linear Algebra Packages in Maple 13, and solvers for algebraic Riccati equations – based on SLICOT Library routines –

have been included in Maple 14 (available in multiple precision arithmetic since Maple 15). Moreover, the MapleSim environment, based on Modelica, enables symbolic simplification, numerical solution of the differential-algebraic equations (DAEs), and model post-processing (sensitivity analysis, linearization, parameter optimization, code generation, etc.). Its Control Design Toolbox provides solutions for optimal control, Kalman filtering, pole assignment, etc. Bidirectional communication with MATLAB is possible.

Compose, OML, and Activate is a new software environment for modelling and simulation (Campbell and Nikoukhah 2019). It is a mixture of open-source and freely distributed software, including Altair ComposeTM, Altair ActivateTM, and Open Matrix Language (OML). Continuous-time, discrete-time, and hybrid systems can be dealt with.

Computational Tools

The computational tools for CACSD implement the main numerical algorithms of the systems and control theory and should satisfy several strong requirements:

- reliability, or guaranteed accuracy, implies the use of numerically stable algorithms as much as possible and the estimation of the problem sensitivity (conditioning) and of the solution accuracy; backward numerical stability ensures that the computed results are exact for slightly perturbed original data;
- robustness, mainly ensured by avoiding overflows, harmful underflows, and unacceptable accumulation of rounding errors; scaling the data may be essential;
- computational efficiency, important for large-scale engineering design problems or for real-time control;
- ease of use, achieved by simplified user interface (hiding the details), and default values for algorithmic parameters, such as tolerances;
- wide scope and rich functionality, which address the range of problems and system representations that can be handled;

- portability to various platforms, in the sense of functional correctness;
- reusability, in building several dedicated software systems or environments.

SLICOT Library (Benner et al. 1999; Van Huffel et al. 2004) is one of the most comprehensive libraries for control theory numerical computations, containing over 550 subroutines which cover system analysis, benchmark and test problems, data analysis, filtering, identification, mathematical routines, some capabilities for nonlinear systems, synthesis, system transformation, and utility routines (see <http://www.slicot.org/>). The requirements above have been taken into account in the SLICOT Library development. Some of the SLICOT components are used in several interactive environments for CACSD, including MATLAB, Maple, Scilab, and Octave *control* package. The library is still under development. It is worth mentioning the recent focus on structure-preserving algorithms, which offer increased accuracy, reliability, and efficiency, in comparison with standard solvers. Many procedures for optimal control and filtering, model reduction, etc. can benefit from using the “structured” solvers. There are also separate SLICOT-based toolboxes for MATLAB (Benner et al. 2010).

SLICOT Library routines, and many functions offered by interactive environments for CACSD, call components from the Basic Linear Algebra Subprograms (BLAS; see Dongarra et al. 1990 and the references therein) and Linear Algebra Package (LAPACK, Anderson et al. 1999). This approach enhances portability and efficiency, since optimized BLAS and LAPACK Libraries are provided for major computer platforms.

Support Tools

The support software tools for CACSD offer additional capabilities compared to computational tools. They may include alternative algorithms, symbolic computations (usually, for low-dimensional problems), extended functionality, e.g., for modelling/simulation of nonlinear systems, code generation, etc. The

support tools can be used by software developers of CACSD environments or computational tools or directly by other users. For instance, symbolic calculations are useful for checking the accuracy of numerical algorithms. The code generation facility offers a safe and convenient support for deploying a design solution to the control hardware. A reference support software tool is briefly presented below.

Dymola (Dynamic modeling Laboratory), from Dassault Systemes (see <https://www.3ds.com/products/catia/portfolio/dymola>), deals with high-fidelity modelling and simulation of complex systems from various domains, like aerospace, automotive, robotics, process control and other applications. Compatible and comprehensive model libraries, developed by leading experts, exist for many engineering branches. The users may create their own libraries or adapt existing libraries. This flexibility and openness is provided by the use of the open, object-oriented modelling language Modelica®, currently further developed by the Modelica Association.

Equation-oriented models, based on DAEs, and symbolic manipulation are used, stimulating the reuse of components and enhancing the reliability and efficiency of the calculations. This approach enables to simplify generating the equations which result from interconnecting various subsystems and to deal with algebraic loops and structurally singular models. Algebraic loops are encountered when some auxiliary variables depend algebraically upon each other in a mutual way (Cellier and Elmqvist 1992). Structural singularities are related to DAE of index higher than 1.

Dymola allows to perform hardware-in-the-loop simulation and real-time 3D animation. A model can be built by graphical composition, connecting components from various libraries using drag-and-drop operations. The parameters a model depends on can be tuned either by *parameter estimation* (also called *model calibration*), which minimizes the error between the physical measurements and simulation results, or by optimization, which minimizes certain performance criteria. Sometimes, e.g., when designing certain controllers, the criteria values are

obtained by simulation. Dymola offers also facilities for model management, including checking, testing, encrypting, or comparing models, and version control.

Summary and Future Directions

The main functional and support facilities offered by interactive environments and software tools for CACSD and reference examples have been presented. Their remarkable evolution during the past decades, combined with the importance of the design solutions they offer, are strong arguments that the CACSD software arsenal will continue to evolve, and more reliable, efficient, and powerful systems will come into place. Progress is expected at all levels, including basic algorithms and numerical and symbolic libraries, but also command languages, user interfaces, human-machine communication, and associated hardware. Tools for adaptive, nonlinear, and distributed control systems design should be developed and integrated. Artificial intelligence support might be required to add expert capabilities to the forthcoming interactive environments. It is expected that deep neural networks will be increasingly used for modelling complex processes.

Recommended Reading

CACSD is well presented in many textbooks. A recent one is Chin (2012), which covers modelling, control system design, implementation, and testing and describes practical applications using MATLAB and Simulink. Many IFAC (International Federation of Automatic Control) and IEEE (The Institute for Electrical and Electronics Engineers, Inc.) international conferences and symposia have been dedicated to CACSD, going back more than three decades. A wealth of material is available, e.g., on the IEEE Xplore (<https://ieeexplore.ieee.org>), containing the proceedings of many of the IEEE CACSD events. A recent event has been the 2016 IEEE Conference on CACSD. Similar IEEE events were regularly held between 1989 and 2013.

Intermittent Image-Based Estimation

Warren E. Dixon

Department of Mechanical and AeroMechanical and Aerospace Engineering, University of Florida, Gainesville, FL, USA

Abstract

Image feedback can be used to estimate Euclidean distances between features in an image and/or relative motion between an image feature and the camera. Typical current methods assume that the image feature is continuously observed; yet, in most practical scenarios, the image feature can be occluded. Image occlusion/intermittency segregates the image dynamics into two subsystems: when the feature is visible, feedback is available and the estimator/observer is stabilizable, otherwise it's unstable. This entry discusses the use of switched/hybrid systems methods including the development of sufficient dwell-time conditions to ensure the stability of such estimators/observers.

Keywords

Nonlinear estimation · Image estimation · Hybrid system · Lyapunov methods · Intermittent sensing

Introduction

Numerous advances have led to widespread adoption of image-based sensing. One of the technical challenges of image-based feedback for navigation and visual servo control for autonomous systems is the lack of depth information (i.e., the distance from the camera to an image feature along

the focal axis), resulting in scale ambiguity. Typical solutions to recover the depth information use multiple views of a feature. Multiple views can be obtained using multiple physical cameras (e.g., a stereo pair) with calibrated relative position and orientation (pose) to determine the properly scaled Euclidean coordinates of image features (i.e., structure estimation) and/or the relative motion between the camera and the feature(s) (i.e., motion estimation) (Faugeras 1993; Hartley and Zisserman 2000; Chaumette and Hutchinson 2006a). Alternatively, monocular solutions use multiple images taken by a moving camera to determine the structure from known motion of the camera (structure from motion (SfM)), or motion from known structure, either using image geometry, provided a sufficient number of features on an object are tracked, or using an estimator/observer (cf. Chaumette et al. 1996; Chaumette and Hutchinson 2006b; Dani et al. 2012; Hu et al. 2008; Dixon et al. 2003). A common assumption among these strategies is that the image features are continuously available.

In many realistic scenarios, image feedback may be intermittent due to failures in feature tracking due to feature occlusions or features leaving the camera field-of-view (FoV) due to motion constraints of the camera or even purposeful motion by the camera. Various path planning and control methods have been motivated by the need to ensure uninterrupted feedback, where the desired trajectory or behavior of such systems is inherently constrained. For example, systems with nonholonomic constraints may experience non-ideal, sharp-angled, or non-smooth trajectories to keep a navigational landmark in the FoV. Moreover, such approaches are still not robust to arbitrary occlusions of the image feature that result from environmental conditions. Typically when features are temporarily not visible, the estimator/observer is reinitialized with the previous state estimate when the feature is reacquired; however, as shown in Liberzon (2003), such switching is insufficient: the estimates may not converge.

In contrast to the strategy of altering the trajectory of the camera to keep the image feature in the FoV, this entry examines recent and

emerging efforts that use switched/hybrid systems methods to examine the stability of image-based estimates in the presence of feature intermittency. These methods include the development of dwell-time conditions that provide sufficient (and potentially conservative) timing conditions which indicate how long features can be occluded, relative to the amount of time the features are visible. A challenge is that image occlusion/intermittency segregates the image dynamics into two subsystems: when the feature is visible, feedback is available and the estimator/observer is stabilizable, otherwise it is unstable. Despite this challenge, tolerance to image feedback intermittency provides inherent robustness to the observer and enables new dwell-time-aware path-planning strategies that ease trajectory generation constraints that require the image feature to remain visible.

Image-Based Estimation Dynamics

The unknown Euclidean coordinates, $X, Y, Z \in \mathbb{R}$, of a tracked feature point can be related to the states of an image-based observer by the normalization $x = [x_1, x_2, x_3]^T \triangleq \left[\frac{X}{Z}, \frac{Y}{Z}, \frac{1}{Z} \right]^T \in \mathbb{R}^3$. Using projective geometry, the measurable image coordinates, $p \in \mathbb{R}^3$, of the feature point can be related to the normalized Euclidean coordinates as $p = A \begin{bmatrix} X \\ Y \\ Z \end{bmatrix}$, where $A \in \mathbb{R}^{3 \times 3}$ is a known, invertible camera intrinsic parameter matrix (Faugeras 1993; Hartley and Zisserman 2000; Chaumette and Hutchinson 2006a). The perspective state dynamics can be written as $\dot{x} = g(t, x)$, where $g(t, x) : [0, \infty) \times \mathbb{R}^3 \rightarrow \mathbb{R}^3$ is a nonlinear function that depends on the partially measurable states (i.e., x_3 is not measurable).

A common objective in image-based navigation and control research is the SfM problem, where the goal of estimating the Euclidean coordinates of the target position can be quantified by the state estimate error

$$e \triangleq x - \hat{x}, \quad (1)$$

where $\hat{x} \in \mathbb{R}^3$ denotes the state estimate provided by an observer. If the image feature is intermit-

tently tracked, then the evolution of e is defined by the family of systems

$$\dot{e} = f_p(t, x, \hat{x}) \quad (2)$$

where $f_p : [0, \infty) \times \mathbb{R}^3 \times \mathbb{R}^3 \rightarrow \mathbb{R}^3$ and $p \in \{s, u\}$, where s is an index for the resulting subsystem when the target is visible and u is an index for the subsystem when the target is not visible. When the target is in view, the first two elements of the state vector x (i.e., x_1 and x_2) are measurable, and the closed-loop error dynamics are

$$f_s = g(t, x) - \dot{\hat{x}}, \quad (3)$$

where $\dot{\hat{x}}$ is defined by an observer. For the error dynamics in (3), numerous observers have been developed that achieve a variety of stability results. However, when the feature is not visible, the state estimates cannot depend on x , and the resulting error system is unstable. For example, a zero order hold (ZOH) could be used (i.e., $\dot{\hat{x}} = 0$), and the unstable error dynamics would be given by

$$f_u = g(t, x). \quad (4)$$

Switched Systems Analysis

Switched systems methods (cf. Liberzon 2003; Goebel et al. 2012) provide an analysis framework to evaluate the stability of state estimation error dynamics in (2) after a series of instances when the image feature is visible or not. The underlying concept is that if the image feature is visible long enough and the instances without feedback are short enough, then the state estimate over the entire trajectory could remain stable. To understand the relative timing for the estimate to be stable, switched systems analysis includes the development of a dwell-time. The dwell-time is typically expressed as a ratio of the time spent in each subsystem, along with the convergence rate in the stable subsystem and the divergence rate in the unstable subsystem. The intermittent

image-based estimation problem is challenging because it inherently involves switching between stabilizable and unstable subsystems, and if the image feature is not visible long enough then stability may never be achieved. Therefore, the concept of an average dwell-time condition (a weaker dwell-time condition where the time in the stable subsystem is longer than the unstable region on average) is difficult to develop. Moreover, when switching between stable and unstable subsystems, two different dwell times are often required, to determine a minimum amount of time to dwell in the stable subsystem and the maximum amount of time in the unstable that can be tolerated. Typically, such dwell-time conditions provide a sufficient rule for a system to follow to ensure stability; however, often for image-based estimation, the ratios of time in each subsystem are arbitrary. In these cases, the dwell-time conditions provide a sufficient condition for a decision-maker to check as a means to trust or not trust the estimated states.

Because the dwell-time conditions are inherently linked to the ratios of the rates of convergence and divergence, exponential stability of the observer is desired. While various exponentially convergent observers have been developed (cf. Chen and Kano 2002; Dani et al. 2012), open questions remain for developing dwell-time conditions for switching between stable and unstable subsystems for asymptotic convergence rates that are more common for the inherently nonlinear image dynamics. Moreover, exponential divergence can also be difficult to determine. For example, in Parikh et al. (2018), the ZOH scenario yielded a faster than exponential divergence rate, which resulted in complex trigonometric dwell-time conditions. However, results such as Parikh et al. (2017) illustrate that by replacing the ZOH observer with a model-based state-predictor during the periods when feedback is unavailable, the divergence rate can be bounded by an exponential envelope, facilitating the development of traditional (and less restrictive) dwell-time conditions. That is, the dwell-time conditions result in the intuitive conclusion that strategies with better state prediction allow the image feature to be occluded for longer periods; however, such

predictors often require more stringent assumptions on knowledge about the camera and image feature relative motion.

Summary and Future Directions

Various strategies are available to analyze image-based estimators in the presence of intermittent visibility of image features. An alternative to the aforementioned switched systems methods is to treat the availability of feedback as a stochastic system with a known distribution and the goal of proving the observer converges in expectation. Another alternative is to develop relationships between multiple visible features, which are assumed to have a constant relative pose, so that when a subset of the features are occluded, the remaining visible features can be used to approximate the trajectory of the hidden features (cf. Mehta et al. 2010). Opportunities also exist to develop such methods within a switched systems framework.

Switched systems methods provide dwell-time conditions that can be checked to determine the stability of image-based observers, with arbitrary loss of features. These conditions also provide design guidelines for potential new advances in image-guided autonomy. Specifically, new image-based path planners could be developed that are informed by the dwell-time conditions to allow the image features to purposefully leave the FoV for controlled periods of time as a means to yield more favorable trajectories. New state-prediction results to minimize the error growth when features are not visible also present new opportunities. With continued development and maturity of switched systems methods (e.g., stochastic switched systems methods), more practical and robust image-based estimation strategies are likely to result.

Inventory Theory

Suresh P. Sethi

Jindal School of Management, The University of Texas at Dallas, Richardson, TX, USA

Abstract

This entry is a brief survey of classical inventory models and their extensions in several directions such as world-driven demands, presence of forecast updates, multi-delivery modes and advanced demand information, incomplete inventory information, and decentralized inventory control in the context of supply chain management. Important references are provided. We conclude with suggestions for future research.

Keywords

EOQ model · Newsvendor model · Base stock policy · (s, S) policy · Incomplete information

Introduction

Optimal inventory theory deals with managing stock levels of goods to effectively meet the demand of those goods. Because of the huge amount of capital that is tied up in inventory,

its management is critical to the profitability of firms. A systematic analysis of inventory problems began with the development of the classical economic order quantity (EOQ) formula of Ford W. Harris in 1913. A substantial amount of research was reported in 1958 by Kenneth J. Arrow, Samuel Karlin, and Herbert Scarf, and much more has accumulated since then. Books on the topic include Zipkin (2000), Porteus (2002), Axsäter (2006), and Bensoussan (2011).

In this entry, we review single- and multi-period models with deterministic, stochastic, partially observed demand for a single product. In these models, our aim is to decide on the time of the orders and the order quantities. The time between issuing an order and its receipt is called the lead time. For most of this review, we will assume the lead time to be zero, and the reader can consult the referenced books for nonzero lead time extensions and other topics not covered here.

Deterministic Demand

We will describe two classical models: the EOQ model and the dynamic lot size model.

The EOQ Model

This basic and most important deterministic model is concerned with a product that has a constant demand rate D in continuous time over an infinite horizon. No shortages are allowed. The costs consist of a fixed setup/ordering cost K and a holding cost h per unit of average on-hand stock per unit time. The production/purchase cost per unit time is a sunk cost since there is no choice of a total amount to produce, and hence it can be ignored. Although dynamic, the model can be reduced to a static model by a simple argument of periodicity. Moreover, it is obvious that one should never produce or order except for when the inventory level is zero, and one should order the same lot size Q each time the inventory level reaches zero. Since the average inventory level over time is $Q/2$ and the number of setups is D/Q per unit time, the long-run average cost to be minimized is $KD/Q + hQ/2$. The optimal policy that minimizes this cost, obtained using

the first-order condition, is to order the lot size

$$Q = \sqrt{\frac{2KD}{h}} \quad (1)$$

every time the inventory level reaches zero. Harris (1913) introduced the model. Erlenkotter (1990) provides a historical account of the formula, and Beyer and Sethi (1998) provide a mathematically rigorous proof involving quasi-variational inequalities (QVI) that arise in the course of dealing with continuous-time optimization problems involving fixed costs.

The Dynamic Lot Size Model

This is an analogue of the EOQ model when the demand varies over time. Wagner and Whitin (1958) developed it in the discrete-time finite horizon framework. With $D(t)$ denoting the demand in period t and other costs similar to those in the EOQ model, they showed that there exists an optimal policy in which an order will be issued just as the inventory level reaches zero, except for the first order. This policy is called the zero-inventory policy. With this in hand, the problem reduces to selecting only the order times. This is accomplished by applying a shortest path algorithm. Moreover, there are forward (recursion) procedures for solving the problem.

An important feature of this model is that in most cases, one can detect a *forecast horizon* which essentially separates earlier periods from later ones. More specifically, T is a forecast horizon if the first order in a T horizon problem remains optimal in any finite horizon problem with horizon longer than T , regardless of the demands beyond the period T . For an extensive bibliography of this literature, see Chand et al. (2002).

Stochastic Demand

We shall discuss three classical models and some of their extensions.

The Single-Period Problem: The Newsvendor Model

The problem of a newsvendor is to decide on an order quantity of newspapers to meet a stochastic demand at a minimum cost. If the realized demand is larger than the ordered quantity, it is lost and there is an opportunity loss of c_u (selling price minus purchase cost) for each paper short. On the other hand, for each paper ordered but not sold, there is an opportunity loss of c_o (purchase cost plus holding cost). The newsvendor conceptualizes the decision by each additional paper as a separate marginal contribution. The first is almost certain to be sold. Each additional paper is less likely to be sold than the previous one. Thus, each additional paper will be worth somewhat less, and the marginal paper at the optimum should be worth exactly zero. Thus, c_u times the probability of selling the marginal paper minus c_o times the probability of not selling it should equal zero. Now, if F denotes the cumulative probability distribution function of the demand D , then clearly the optimal order quantity Q satisfies $c_o \cdot F(Q) - c_u \cdot (1 - F(Q)) = 0$, which gives us the famous newsvendor formula for the optimal order quantity

$$Q = F^{-1}\left(\frac{c_u}{c_u + c_o}\right), \quad (2)$$

where $c_u/(c_u + c_o)$ is known as the critical fractile.

If p denotes the unit sale price, c the unit cost, and h the holding cost per unit per unit time, then $c_u = p - c$ and $c_o = c + h$, and therefore, the critical fractile can be expressed as $(p - c)/(p + h)$. An extension of the newsvendor formula to allow for a unit cost g of lost goodwill and a unit salvage value s received at the end of the period for each unit not sold is immediate. If we let $\alpha > 0$ denote the periodic discount factor, then $c_u = p + g - c$ and $c_o = c + h - \alpha s$ and the critical fractile becomes $(p + g - c)/(p + g + h - \alpha s)$, and therefore,

$$Q = F^{-1}\left(\frac{p + g - c}{p + g + h - \alpha s}\right). \quad (3)$$

The newsvendor model has been used extensively in the context of supply chain management with multiple agents maximizing their individual objectives. In this case, inefficiencies arise due to double marginalization. Then, a question of appropriate contracts that can lead to the first-best solution, or coordinate the supply chain, becomes important. Cachon (2003) surveys this literature.

Multi-period Inventory Models: No Fixed Cost

The newsvendor model is a single-period model, and its multi-period generalization requires that the inventory not sold in a period is carried over to the next period. This results in the multi-period inventory model with lost sales. It is assumed that demand in each period is independent and identically distributed (i.i.d.) with F denoting its cumulative probability distribution function. A rigorous analysis requires the method of dynamic programming, and it shows that there is a stock level S_t called *base stock* in period t , that we would ideally like to have at the beginning of period t . Thus, the optimal policy in period t , called *the base stock policy*, is to order

$$Q_t(x) = \begin{cases} S_t - x & \text{if } x < S_t, \\ 0 & \text{if } x \geq S_t. \end{cases} \quad (4)$$

In the special case when the terminal salvage value of an item is exactly equal to its cost c , it is possible to come up with the optimal policy using intuition. Since we do not need to salvage unused items in the multi-period setting, one can argue that an item carried over to the next period is worth its purchase cost c . Therefore, its presence means that the next period will need to order one less and thus save an amount c . In the last period, when there is no next period, our terminal salvage value assumption also guarantees a leftover item's worth to be also c . Thus, we can modify (3) and obtain a stationary base stock level

$$\begin{aligned} S &= F^{-1} \left(\frac{p + g - c}{(p + g - c) + (c + h - \alpha c)} \right) \\ &= F^{-1} \left(\frac{p + g - c}{p + g + h - \alpha c} \right) \end{aligned} \quad (5)$$

for each period t .

Thus, the elimination of the endgame effect delivers us a *myopic policy*, a policy optimal in the single-period case to be also optimal in the dynamic multi-period setting. A more general concept than the optimality of a myopic policy is that of the forecast horizon mentioned earlier in the context of the dynamic lot size model.

Sometimes, when the demand exceeds the on-hand inventory in the period, the demand is not lost but backlogged. In this case, each unit of backlogged demand is satisfied in the next period, and unit revenue p is recovered, but a unit backlogging cost b is incurred, due to expediting, special handling, delayed receipt of revenue, and loss of goodwill. Thus, $c_u = b - (1 - \alpha)c$, where the second term represents the savings due to postponing the purchase of the backlogged demand unit by one period, and $c_o = c + h - \alpha c$ as in (4). This gives us the base stock level

$$S = F^{-1} \left(\frac{b - (1 - \alpha)c}{b + h} \right), \quad (6)$$

which can be used in (5) to give the optimal policy.

Sometimes it is possible to have multiple delivery modes such as fast, regular, and slow as well as demand forecast updates. Then, at the beginning of each period, on-hand inventory and demand information are updated. At the same time, decisions on how much to order using each of the modes are made. Fast, regular, and slow orders are delivered at the ends of the current, the next, and one beyond the next periods, respectively. In such models, a modified base stock policy is optimal only for the two fastest modes. For details and further generalization, see Sethi et al. (2005).

An important extension includes serial inventory systems where stage 1 receives supplies from an outside source and each downstream stage receives supplies from its immediate upstream stage. Clark and Scarf (1960) introduced the notion of the echelon inventory position at a stage to consist of the stock at that stage plus stock in transit to that stage plus all downstream stock minus the amount backlogged at the final stage. Then, the optimal ordering policy at each stage

is given by an echelon base stock policy with respect to the echelon inventory position at that stage. It is known that assembly systems can be reduced to a serial system. Details can be found in Zipkin (2000).

Multi-period Inventory Models: Fixed Cost

When there is a fixed cost of ordering, it is clear that it would not be reasonable to follow the base stock policy when the inventory level is not much below the base stock level. Indeed, Scarf (1960) proved that there are numbers s_t and S_t , $s_t < S_t$, for period t such that the optimal policy in period t is to order

$$Q_t(x) = \begin{cases} S_t - x & \text{if } x \leq s_t \\ 0 & \text{if } x > s_t. \end{cases} \quad (7)$$

Such a policy is famously known as an (s, S) policy.

When the demands are not i.i.d., the model has been extended to Markovian demands. In this case, there is an exogenous Markov process, and the distribution of the demand in each period depends on the state of the Markov process, called the demand state, in that period. It can be shown that the optimal policy in period t is (s_t^i, S_t^i) , where i denotes the demand state in the period. Such a policy is also called a state-dependent (s, S) policy. Further details are available in Beyer et al. (2010). Recent advances in information technology have allowed managers to obtain advance demand information in addition to forecast updates. In such cases, a state-dependent (s, S) policy can be shown to be optimal. For details, refer to Ozer (2011).

The Continuous-Time Model: Fixed Cost

The marriage of the two classical results (1) and (7) is accomplished by Presman and Sethi (2006) in a continuous-time stochastic inventory model involving a demand that is the sum of a constant demand rate and a compound Poisson process. The optimal policies that minimize a discounted cost or the long-run average cost are both of (s, S) type. The (s, S) policy minimizing the long-run average cost reduces to the EOQ formula when the intensity of the com-

pound Poisson process is set to zero. And when the constant demand component vanishes, the model reduces to the continuous-review stochastic inventory model with fixed cost and compound Poisson demand.

Incomplete Inventory Information Models (i3)

A critical assumption in the vast inventory theory literature has been that the level of inventory at any given time is fully observed. The celebrated results (1) and (7) have been obtained under the assumption of full observation. Yet the inventory level is often not fully observed in practice, for a variety of reasons such as replenishment errors, employee theft, customer shoplifting, improper handling and damaging of merchandise, misplaced inventories, uncertain yield, imperfect inventory audits, and incorrect recording of sales. In such an environment of incomplete information, inventories are known to be partially observed and most of the well-known inventory policies including (1) and (7) are not even admissible, let alone optimal. In such cases, Bensoussan et al. (2010) show that the dynamic programming equation can be written in terms of the unnormalized conditional probability of the current inventory level given past observations, referred to as signals, instead of just the inventory level in the full observation case. Furthermore, one can write the evolution of the conditional probability in terms of its current value, the current order, and the current observation. However, there are no longer simple optimal policies except in cases of information delay reported in Bensoussan et al. (2009) and demands are observed to learn about an unknown parameter of the demand distribution Bensoussan et al. (2019) where modified base stock and (s, S) policies are shown to be optimal.

Summary and Future Directions

We briefly describe some classical results in inventory theory. These are based on full observation. Some recent work on inventory models under incomplete information is reported.

This work leads to a number of new research directions, both theoretical and empirical as reported in Sethi (2010). It would be of much interest to know the industries where the i3 problem is serious enough to warrant the difficult mathematical analysis required. Furthermore, how are the observed signals related to the inventory level? It is also clear from the reviewed literature that there are no simple optimal policies for most i3 problems, so it would be important to develop efficient computational procedures to obtain optimal solutions or to specify a class of simple implementable policies and optimize within this class. An important benefit of solving i3 problems optimally is the provision of an economic justification for technologies such as RFID that may reduce inaccuracies in inventory observations.

Another area of research would be to study multi-period multi-agent supply chains with a stochastic inventory dynamics. While these can be formulated as dynamic games, there are a number of equilibrium concepts to deal with, depending on the information the agents have. Some of them are time consistent or subgame perfect and some are not. Regardless, there are inefficiencies that arise from these decentralized game settings, and developing contracts for coordinating dynamic supply chains remains a wide open topic of research.

Investment-Consumption Modeling

L. C. G. Rogers

University of Cambridge, Cambridge, UK

Abstract

The simplest investment-consumption problem is the celebrated example of Robert Merton (J Econ Theory 3(4):373–413, 1971). This survey shows three different ways of solving the problem, each of which is a valuable solution method for more complicated versions of the question.

Keywords

Budget constraint ·
Hamilton-Jacobi-Bellman (HJB) equation ·
Merton problem · Value function

Introduction

Consider an investor in a market with a riskless bank account accruing continuously compounded interest at rate r_t , and with a single risky asset whose price S_t at time t evolves as

$$dS_t = S_t(\sigma_t dW_t + \mu_t dt), \quad (1)$$

where W is a standard Brownian motion, and σ and μ are processes previsible with respect to the filtration of W . The investor starts with initial wealth w_0 and chooses the rate c_t of consuming, and the wealth θ_t to invest in the risky asset, so that his overall wealth evolves as

$$\begin{aligned} dw_t &= \theta_t(\sigma_t dW_t + \mu_t dt) + r_t(w_t - \theta_t)dt - c_t dt \\ &= r_t w_t dt + \theta_t\{\sigma_t dW_t + (\mu_t - r_t)dt\} - c_t dt. \end{aligned} \quad (2)$$

(3)

For convenience, we assume that σ , σ^{-1} , and μ are bounded. See Rogers and Williams

(2000a, b) for background information on stochastic processes. The three terms in (2) have natural interpretations: The first expresses the evolution of the wealth invested in the stock, the second the interest accruing on the wealth $(w - \theta)$ invested in the bank account, and the third is the cash being withdrawn for consumption.

To avoid so-called doubling strategies, we insist that the wealth process so generated by the controls (c, θ) must remain bounded below in some suitable way, which here is just the condition $w_t \geq 0$ for all $t \geq 0$; any (c, θ) satisfying this condition will be called *admissible*. The set of admissible (c, θ) will be denoted $\mathcal{A}(w_0)$, a notation which makes explicit the dependence on the investor's initial wealth.

The investor's objective is taken to be to obtain

$$V(w_0) \equiv \sup_{(c, \theta) \in \mathcal{A}(w_0)} E \left[\int_0^\infty e^{-\rho t} U(c_t) dt \right] \quad (4)$$

for some constant $\rho > 0$. The problem cannot be solved explicitly at this level of generality, but if we take some special cases, we are able to illustrate the main methods used to attack it. Many other objectives with various different constraints can be handled by similar techniques: see Rogers (2013) for a wide range of examples.

The Main Techniques

We present here three important techniques for solving such problems: the value function approach; the use of dual variables; and the use of martingale representation. The first two methods only work if the problem is Markovian; the third only works if the market is complete. There is a further method, the Pontryagin-Lagrange approach; see Sect. 1.5 in Rogers (2013). While this is a quite general approach, we can only expect explicit solutions when further structure is available.

The Value Function Approach

To illustrate this, we focus on the original Merton problem (Merton 1971), where σ and μ are both constant, and the utility U is constant relative risk

aversion (CRRA):

$$U'(x) = x^{-R} \quad (x > 0) \quad (5)$$

for some $R > 0$ different from 1. The case $R = 1$ corresponds to logarithmic utility, and can be solved by similar methods. Perhaps the best starting point is the *Davis-Varaiya Martingale Principle of Optimal Control (MPOC)*: The process $Y_t = e^{-\rho t} V(w_t) + \int_0^t e^{-\rho s} U(c_s) ds$ is a supermartingale under any control, and a martingale under optimal control. If we use Itô's formula, we find that

$$\begin{aligned} e^{\rho t} dY_t &= -\rho V(w_t)dt + V'(w_t)dw_t \\ &\quad + \frac{1}{2}\sigma^2\theta_t^2 V''(w_t)dt + U(c_t)dt \\ &\doteq [-\rho V + \{\theta_t(\mu - r) - c_t + r\}V' \\ &\quad + \frac{1}{2}\sigma^2\theta_t^2 V'' + U(c_t)] dt, \end{aligned} \quad (6)$$

where the symbol $\doteq$ denotes that the two sides differ by a (local) martingale. If the MPOC is to hold, then we expect that the drift in dY should be non-positive under any control, and equal to zero under optimal control. We simply assume for now that local martingales are martingales; this is of course not true in general, and is a point that needs to be handled carefully in a rigorous proof. Directly from (6), we then deduce the *Hamilton-Jacobi-Bellman (HJB) equations* for this problem:

$$\begin{aligned} 0 = \sup_{c, \theta} [-\rho V + \{\theta(\mu - r) - c + r\}V' \\ + \frac{1}{2}\sigma^2\theta^2 V'' + U(c)]. \end{aligned} \quad (7)$$

Write $\tilde{U}(y) \equiv \sup \{U(x) - xy\}$ for the convex dual of U , which in this case has the explicit form

$$\tilde{U}(y) = -\frac{y^{1-R'}}{1-R'} \quad (8)$$

with $R' \equiv 1/R$. We are then able to perform the optimizations in (7) quite explicitly to obtain

$$0 = -\rho V + rV' + \tilde{U}(V') - \frac{1}{2} \kappa^2 \frac{(V')^2}{V''} \quad (9)$$

where

$$\kappa \equiv \frac{\mu - r}{\sigma}. \quad (10)$$

Nonlinear PDEs arising from stochastic optimal control problems are not in general easy to solve, but (9) is tractable in this special setting, because the assumed CRRA form of U allows us to deduce by a scaling argument that $V(w) \propto w^{1-R} \propto U(w)$, and we find that

$$V(w) = \gamma_M^{-R} U(w), \quad (11)$$

where

$$R\gamma_M = \rho + (R-1)(r + \frac{1}{2}\kappa^2/R). \quad (12)$$

The optimal investment and consumption behavior is easily deduced from the optimal choices which took us from (7) to (9). After some calculations, we discover that

$$\theta_t^* = \pi_M w_t \equiv \frac{\mu - r}{\sigma^2 R} w_t, \quad c_t^* = \gamma_M w_t \quad (13)$$

specifies the optimal investment/consumption behavior in this example. (The positivity of γ_M is necessary and sufficient for the problem to be well posed; see Sect. 1.6 in Rogers 2013). Unsurprisingly, the optimal solution scales linearly with wealth.

Dual Variables

We illustrate the use of dual variables in the constant-coefficient case of the previous section, except that we no longer suppose the special form (5) for U . The analysis runs as before all the way to (9), but now the convex dual $\tilde{U}$ is not simply given by (8). Although it is not now possible to guess and verify, there is a simple transformation which reduces the nonlinear ODE (9) to something we can easily handle. We introduce the new variable $z > 0$ related to w by $z = V'(w)$, and define a function J by

$$J(z) = V(w) - wz. \quad (14)$$

Simple calculus gives us $J' = -w$, $J'' = -1/V''$, so that the HJB equation (9) transforms

into

$$0 = \tilde{U}(z) - \rho J(z) + (\rho - r)zJ'(z) + \frac{1}{2}\kappa^2 z^2 J''(z), \quad (15)$$

which is now a second-order *linear* ODE, which can be solved by traditional methods; see Sect. 1.3 of Rogers (2013) for more details.

Use of Martingale Representation

This time, we shall suppose that the coefficients μ_t , r_t , and σ_t in the wealth evolution (3) are general previsible processes; to keep things simpler, we shall suppose that μ , r , and σ^{-1} are all bounded previsible processes. The Markovian nature of the problem which allowed us to find the HJB equation in the first two cases is now destroyed, and a completely different method is needed. The way in is to define a positive semimartingale ζ by

$$d\zeta_t = \zeta_t (-r_t dt - \kappa_t dW_t), \quad \zeta_0 = 1 \quad (16)$$

where $\kappa_t = (\mu_t - r_t)/\sigma_t$ is a previsible process, bounded by hypothesis. This process, called the *state-price density process*, or the *pricing kernel*, has the property that if w evolves as (3), then $M_t \equiv \zeta_t w_t + \int_0^t \zeta_s c_s ds$ is a positive local martingale.

Since positive local martingales are supermartingales, we deduce from this that

$$M_0 = w_0 \geq E \left[\int_0^\infty \zeta_s c_s ds \right]. \quad (17)$$

Thus, for any $(c, \theta) \in \mathcal{A}(w_0)$, the budget constraint (17) must hold. So the solution method here is to maximize the objective (4) subject to the constraint (17). Absorbing the constraint with a Lagrange multiplier λ , we find the unconstrained optimization problem

$$\sup E \left[\int_0^\infty \{e^{-\rho s} U(c_s) - \lambda \zeta_s c_s\} ds \right] + \lambda w_0 \quad (18)$$

whose optimal solution is given by

$$e^{-\rho s} U'(c_s) = \lambda \zeta_s, \quad (19)$$

and this determines the optimal c , up to knowledge of the Lagrange multiplier λ , whose value is fixed by matching the budget constraint (17) with equality.

Of course, the missing logical piece of this argument is that if we are given some $c \geq 0$ satisfying the budget constraint, is there necessarily some θ such that the pair (c, θ) is admissible for initial wealth w_0 ? In this setting, this can be shown to follow from the Brownian integral representation theorem, since we are in a complete market; however, in a multidimensional setting, this can fail, and then the problem is effectively insoluble.

Summary and Future Directions

This brief survey states some of the main ideas of consumption-investment optimization, and sketches some of the methods in common use. Explicit solutions are rare, and much of the interest of the subject focuses on efficient numerical schemes, particularly when the dimension of the problem is large. A further area of interest is in continuous-time principal-agent problems; Cvitanic and Zhang (2012) is a recent account of some of the methods of this subject, but it has to be said that the theory of such problems is much less complete than the simple single-agent optimization problems discussed here.

Iterative Learning Control

David H. Owens

Zhengzhou University, Zhengzhou, P.R. China
Automatic Control and Systems Engineering,
University of Sheffield, Sheffield, UK

Abstract

Iterative learning control addresses tracking control where the repetition of a task allows improved tracking accuracy from task to task. The area inherits the analysis and design issues of classical control but adds convergence conditions for task to task learning, the need for acceptable task-to-task performance and the implications of modelling errors for task-to-task robustness.

Keywords

Iterative learning control · Iteration · Adaptation · Repetition · Optimization · Robustness

Introduction

Iterative learning control (ILC) is relevant to trajectory tracking control problems on a finite interval $[0, T]$ (Bien and Xu 1998; Chen and Wen 1999; Ahn et al. 2007b; Owens 2016). It has close links to multipass process theory (Edwards and Owens 1982) and repetitive control (Rogers et al. 2007) plus conceptual links to adaptive control. It focusses on problems where the repetition of a specified task creates the possibility of improving tracking accuracy from task to task

and, in principle, reducing the tracking error to exactly zero. The iterative nature of the control schemes proposed the use of past executions of the control to update/improve control action, and the asymptotic learning of the required control signals puts the topic in the area of adaptive control although other areas of study are reflected in its methodologies.

Application areas are many and include robotic assembly (Arimoto et al. 1984), electromechanical test systems (Daley et al. 2007) and medical rehabilitation robotics (Rogers et al. 2010). For example, consider a manufacturing robot required to undertake an indefinite number of identical tasks (such as “pick and place” of components) specified by a spatial or temporal trajectory on a defined time interval. The problem is two-dimensional. More precisely, the controlled system evolves with *two* variables, namely, time $t \in [0, T]$ (elapsed in each iteration) and iteration index $k \geq 0$. Data consists of signals $f_k(t)$ giving the value of the signal f at time t on iteration k . The conceptual algorithm used is (Owens 2016):

Step one: (Preconditioning) Implement loop controllers to condition plant dynamics.

Step two: (Initialization) Given a demand signal $r(t)$, $t \in [0, T]$, choose an initial input $u_0(t)$, $t \in [0, T]$ and set $k = 0$.

Step three: (Response measurement) Return the plant to a defined initial state. Find the output response y_k to the input u_k . Construct the tracking error $e_k = r - y_k$. Store data.

Step four: (Input signal update) Use past records of inputs used and tracking errors generated to construct a new input $u_{k+1}(t)$, $t \in [0, T]$ to be used to improve tracking accuracy on the next trial.

Step five: (Termination/task repetition?) Either terminate the sequence or increase k by unity and return to step 3.

It is the updating of the input signal based on observation that provides the conceptual link to adaptive control. ILC *causality* defines *past data* at time t on iteration k as data on the interval $[0, t]$ on that iteration plus all data on $[0, T]$ on all previous iterations. Feedback plus

feedforward control is the name given to a control policy that uses real-time feedback of current iteration measurements and feedforward transfer of information from past iterations to the current iteration.

Modelling Issues

Design approaches have been model-based. Most non-linear problems assume non-linear-state space models relating the $\ell \times 1$ input vector $u(t)$ to the $m \times 1$ output vector $y(t)$ via an $n \times 1$ state vector $x(t)$ as follows:

$$\dot{x}(t) = f(x(t), u(t)), \quad y(t) = h(x(t), u(t)),$$

where $t \in [0, T]$, $x(0) = x_0$ and f and h are vector-valued functions. The discrete time (sample data) version replaces derivatives by a forward shift, where t is now a sample counter, $0 \leq t \leq N$. The continuous time linear model is:

$$\dot{x}(t) = Ax(t) + Bu(t), \quad y(t) = Cx(t) + Du(t)$$

with an analogous model for discrete systems. In both case the matrices A, B, C, D are constant or time varying matrices of appropriate dimension.

Non-linear systems present the greatest technical challenge. Linear system's challenges are greater for the time varying, continuous time case. The simplest linear case of discrete time, time-invariant systems, can be described by a matrix relationship:

$$y = Gu + d \quad (1)$$

where y denotes the $m(N+1) \times 1$ "supervector" generated by the time series $y(0), y(1), \dots, y(N)$ and the construction $y = [y^T(0), y^T(1), \dots, y^T(N)]^T$, the supervector u is generated, similarly, by the time series $u(0), u(1), \dots, u(N)$, and d is generated by the times series $Cx_0, CAx_0, \dots, CA^N x_0$. The matrix G has the lower block triangular structure:

$$G = \begin{bmatrix} D & 0 & 0 & \dots & 0 \\ CB & D & 0 & \dots & 0 \\ CAB & CB & D & \dots & 0 \\ \vdots & & & & \\ CA^{N-1}B & CA^{N-2}B & \dots & D \end{bmatrix}$$

defined in terms of the Markov parameter matrices $D, CB, CAB, \dots$ of the plant. This structure has led to a focus on the discrete time, time invariant case and exploitation of matrix algebra techniques.

More generally, $G : \mathcal{U} \rightarrow \mathcal{Y}$ can be a bounded linear operator between suitable signal spaces $\mathcal{U}$ and $\mathcal{Y}$. Taking G as a convolution operator, the representation (1) also applies to time-varying continuous time and discrete time systems. The representation also applies to differential-delay systems, coupled algebraic and differential systems, multi-rate systems and other situations of interest.

Formal Design Objectives

Problem statement: Given a reference signal $r \in \mathcal{Y}$ and an initial input signal $u_0 \in \mathcal{U}$, construct a causal control update rule/algorithm:

$$u_{k+1} = \psi_k(e_{k+1}, e_k, \dots, e_0, u_k, u_{k-1}, \dots, u_0)$$

that ensures that $\lim_{k \rightarrow \infty} e_k = 0$ (convergence) in the norm topology of $\mathcal{Y}$.

The update rule $\psi_k(\cdot)$ represents the simple idea of expressing u_{k+1} in terms of past data. A general linear "high order" rule is:

$$u_{k+1} = \sum_{j=0}^k W_j u_{k-j} + \sum_{j=0}^{k+1} K_j e_{k+1-j} \quad (2)$$

with bounded linear operators $W_j : \mathcal{U} \rightarrow \mathcal{U}$ and $K_j : \mathcal{Y} \rightarrow \mathcal{U}$, regarded as compensation elements and/or filters to condition the signals. Typically $K_j = 0$ (resp. $W_j = 0$) for $j > M_e$ (resp. $j > M_u$). A simple structure is:

$$u_{k+1} = W_0 u_k + K_0 e_{k+1} + K_1 e_k \quad (3)$$

Assuming that G and W_0 commute (i.e. $GW_0 = W_0G$), the resultant error evolution takes the form:

$$e_{k+1} = (I + GK_0)^{-1}(W_0 - GK_1)e_k \\ + (I + GK_0)^{-1}(I - W_0)(r - d)$$

which relates errors on each iteration via the recursive structure:

$$e_{k+1} = Le_k + d_0. \quad (4)$$

Equations of this type (and their non-linear counterparts) play a central role throughout the subject area.

Robust ILC: An ILC algorithm is said to be robust if convergence is retained in the presence of a defined class of modelling errors.

Results from multipass systems theory (Edwards and Owens 1982) indicate robust convergence of the sequence $\{e_k\}_{k \geq 0}$ to a limit $e_\infty \in \mathcal{Y}$ (in the presence of small modelling errors) if the spectral radius condition:

$$r(L) = r[(I + GK_0)^{-1}(W_0 - GK_1)] < 1 \quad (5)$$

is satisfied where $r[\cdot]$ denotes the spectral radius of its argument. However, the desired condition $e_\infty = 0$ is true only if $W_0 = I$ (when $d_0 = 0$). For a given r , it may be possible to retain the benefits of choosing $d_0 \neq 0$ (i.e. $W_0 \neq I$) and still ensure that e_∞ is sufficiently small for the application in mind, e.g. by limiting limit errors to a high frequency band. This and other spectral radius conditions form the underlying convergence condition when choosing controller elements but are rarely computed. The simplest algorithm using eigenvalue computation for a linear discrete time system defines the *relative degree* to be $k^* = 0$ if $D \neq 0$ and the smallest integer k such that $CA^{k-1}B \neq 0$ otherwise. Replacing $\mathcal{Y}$ by the range of G , choosing $W_0 = I$, $K_0 = 0$ and $K_1 = I$ and supposing that $k^* \geq 1$, the Arimoto input update rule $u_{k+1}(t) = u_k(t) + e_k(t + k^*)$, $0 \leq t \leq N + 1 - k^*$ provides robust convergence if, and only if, $r[I - CA^{k^*-1}B] < 1$. It does not imply that the error signal necessarily improves

each iteration. Errors can reach very high values before finally converging to zero. However, if (5) is replaced by the operator norm condition:

$$\|(I + GK_0)^{-1}(W_0 - GK_1)\| < 1, \quad \text{then} \quad (6)$$

$\{\|e_k - e_\infty\|_Q\}_{k \geq 0}$ monotonically decreases to zero.

The spectral radius condition throws light on the nature of ILC robustness. Choosing, for simplicity, $K_0 = 0$ and $W_0 = I$, the requirement that $r[I - GK_1] < 1$ will be satisfied by a wide range of processes G , namely, those for which the eigenvalues of $I - GK_1$ lie in the open unit circle of the complex plane. Translating this requirement into useful robustness tests may not be easy in general. The discussion does however show that the behaviour of GK_1 must be “sign definite” to some extent, as if $r[I - GK_1] < 1$, then $r[I - (-G)K_1] > 1$, i.e., replacing the plant by $-G$ (no matter how small) will inevitably produce non-convergent behaviour. A more detailed characterization of this property is possible for inverse model ILC (Owens 2016).

Inverse Model-Based Iteration

If $m = \ell$ and a linear system G has a well-defined inverse model G^{-1} , then the required input signal to produce zero tracking error is $u_\infty = G^{-1}(r - d)$. The simple update rule:

$$u_{k+1} = u_k + \beta G^{-1}e_k, \quad (7)$$

where β is a *learning gain*, produces the dynamics:

$$e_{k+1} = (1 - \beta)e_k \quad \text{or} \quad e_{k+1} = (1 - \beta)^k e_0,$$

proving that zero error is attainable with added flexibility in convergence rate control by choosing $\beta \in (0, 2)$. The convergence then takes the form of a *monotonic* reduction in error magnitude. Errors in the system model used in (7) are an issue. Insight into this problem is easily obtained for single-input, single-output discrete time systems with multiplicative plant uncertainty U as

retention of monotonic convergence is ensured (Owens 2016; Owens and Chu 2012) by a frequency domain condition:

$$|\frac{1}{\beta} - U(e^{i\theta})| < \frac{1}{\beta}, \text{ for all } \theta \in [0, 2\pi] \quad (8)$$

that illustrates a number of general empirical rules for ILC robust design. The first is that a small learning gain (and hence small input update changes and slow convergence) will tend to increase robustness and, hence, that it is *necessary* that multiplicative uncertainties satisfy some form of strict positive real condition which, for (7), is:

$$\operatorname{Re} [U(e^{i\theta})] > 0, \text{ for all } \theta \in [0, 2\pi], \quad (9)$$

a condition that limits high-frequency roll-off error and constrains phase errors to the range $(-\frac{\pi}{2}, \frac{\pi}{2})$. The second observation is that, if G is non-minimum-phase, the inverse G^{-1} is unstable, a situation that cannot be tolerated in practice.

The case of multi-input, multi-output (MIMO) systems with a left and/or a right inverse is analysed in detail in Owens (2016) with monotonic robustness being described by an operator inequality that, for state space systems, becomes a frequency-dependent matrix inequality.

Optimization-Based Iteration

Design criteria can be strengthened by a monotonicity requirement. Measuring error magnitude by a norm $\|e\|_Q$ on $\mathcal{Y}$, such as the weighted mean square error (with Q symmetric, positive definite):

$$\|e\|_Q = \sqrt{\int_0^T e^T(t) Q e(t) dt},$$

then the monotonicity condition $\|e_{k+1}\|_Q < \|e_k\|_Q$ for all $k \geq 0$ provides a performance improvement from iteration to iteration. This idea

leads to a number of design approaches (Owens and Daley 2008) and, more extensively, in the texts (Ahn et al. 2007b; Owens 2016) (which also characterize aspects of robustness).

Function/Time Series Optimization

Control algorithms that reduce the error norm monotonically are, implicitly, searching for the minimum achievable error e_∞ satisfying:

$$\|e_\infty\| = \min\{\|e\| : e = r - y\}$$

subject to the dynamical constraint $y = Gu + d$. That is, iterative learning control has a natural link to optimization theory and algorithms.

The idea of gradient-based control (Owens 2016) takes the form, for linear models (1):

$$u_{k+1} = u_k + \beta G^* e_k$$

where $G^* : \mathcal{Y} \rightarrow \mathcal{U}$ is the adjoint operator of G and β is a scalar gain (sometimes called the step size). The error evolution takes the form:

$$e_{k+1} = (I - \beta G G^*) e_k.$$

As a consequence, monotonic reductions are achieved if β lies in the range:

$$0 < \beta < \frac{2}{\|G^*\|^2}.$$

For state space systems, the norm $\|G^*\|$ can be computed from frequency response data, and robust, monotonic convergence is achieved if a frequency-dependent matrix inequality is satisfied.

Norm optimal ILC (NOILC) (Owens 2016; Owens and Daley 2008) guarantees monotonicity and convergence to $e_\infty = 0$ by computing u_{k+1} to minimize an objective function:

$$J(u) = \|e\|_Q^2 + \|u - u_k\|_R^2,$$

subject to plant dynamics. The additional input-dependent term is there to influence the magnitude of the change in control of each iteration.

For linear models (1):

$$u_{k+1} = u_k + G^* e_{k+1}.$$

For continuous or discrete time linear-state space models, the problem is a classical optimal tracking problem with a solution consisting of online, current iteration-state feedback and a feedforward term generated offline by simulation of an “adjoint” model using the previous iteration data e_k and u_k . Reducing R in J leads to faster convergence rates but higher gains. The presence of non-minimum-phase zeros also has a negative effect on convergence (Owens and Chu 2010; Owens 2016). Monotonicity and convergence to zero are retained, but, after an initial fall, the error norm then reduces infinitesimally each iteration producing the practical effect of limited error reductions over finite iteration horizons. Rules exist, Owens and Chu (2010) and Owens (2016), to minimize the effect by choice of initial input u_0 and the reference signal r .

Related Linear NOILC Problems

If $\mathcal{Y}$ and $\mathcal{U}$ are real Hilbert spaces, geometrical arguments can be used (Owens 2016) to generate algorithms extending the NOILC algorithm to include *acceleration mechanisms, predictive control and the inclusion of input signal constraints*. They also allow more flexibility in the form of task specification.

In the *intermediate point NOILC problem* (denoted IPNOILC), the task requirement is that the output signal $y(t)$, $0 \leq t \leq T$ takes specified values $r(t_1), r(t_2), \dots, r(t_M)$ as it passes through the M intermediate points $0 < t_1 < t_2 < \dots < t_M$. The precise nature of the trajectory between points is of secondary importance. Again, the solution, for linear-state space systems, can be constructed from Riccati equation-based feedback rules combined with “jump” conditions and feedforward control signals computed offline. The IPNOILC solution is non-unique, and the remaining degrees of freedom can be used to satisfy other design objectives. Switching algorithms (Owens et al.

2013) converge to a solution of the problem whilst simultaneously minimizing an auxiliary criterion:

$$J_{\text{aux}}(u) = \|z - z_0\|_Q^2 + \|u - u_0\|_R^2.$$

Auxiliary optimization is a tool for shaping the solution of the IPNOILC problem. The auxiliary variable z could be internal states whose behaviour is important to plant operation or simply defined by the output, e.g. $z = \ddot{y}$, which, if small, might reduce input “forces” and hence actuator activity.

Each algorithm has the effect of producing a different form of the evolution operator L . This operator and its spectrum describe the properties of the algorithm. Other algorithms (Owens 2016) such as the “notch” algorithm annihilate parts of the spectrum in one iteration, opening up the possibility of sequentially, selectively and rapidly reducing errors in defined frequency ranges.

Parameter Optimization

NOILC can be simplified by reducing the degrees of freedom defining control action to a small number of control law parameters. For a discrete system (1), a general update rule is:

$$u_{k+1} = u_k + \Gamma(\beta_{k+1})e_k, \quad k \geq 0.$$

Here the matrix $\Gamma(\beta)$ is linear in the $p \times 1$ parameter vector β with $\Gamma(0) = 0$. Under these conditions $\Gamma(\beta)e = F(e)\beta$ where the matrix $F(e)$ is linear in e with $F(0) = 0$. Examples of useful parameterizations include inverse model control (Owens et al. 2012).

Monotonicity of the error norm is ensured by choosing the parameter vector β_{k+1} to minimize:

$$J(\beta) = \|e\|_Q^2 + \beta^T W_{k+1} \beta$$

subject to the dynamic constraint (1). Each $p \times p$ weighting matrix W_{k+1} is symmetric and positive definite and may be iteration dependent. The algorithm creates a non-linear ILC law providing a link between parameter evolution, past errors and the choice of weight W_{k+1} .

Summary and Future Directions

The basic structure of ILC is now well-understood with a number of algorithms available with known convergence properties and empirical links between parameter choice and convergence rates (Bristow et al. 2006; Ahn et al. 2007a; Wang et al. 2009; Xu 2011; Owens and Daley 2008; Owens 2016). Optimization-based algorithms provide a structured approach to convergence and have a familiar quadratic optimal control structure. Despite the practical benefits of monotonic error norms, this approach underlines the difficulties induced by non-minimum-phase (NMP) properties of the plant. Operator representations extend this theory to more general problems such as the intermediate point tracking problem and, where solutions are non-unique, can be converted into iterative algorithms that inherit the properties of NOILC but converge to a solution that also minimizes an auxiliary optimization criterion.

Many of the challenges addressed by NOILC are inherited by other algorithms, many of which mimic established control design paradigms. For example, the commonly used *PD update law*:

$$u_{k+1}(t) = u_k(t) + K_1 e_k(t) + K_2 \dot{e}_k(t)$$

can produce convergence by suitable choice of K_1 and K_2 . Proofs of convergence are typically based on spectral radius conditions similar to (5) for linear systems or on techniques such as contraction mapping (fixed point) theorems (Xu 2011) for non-linear systems. The non-linear case generally suggests *local* convergence conditions dependent on growth conditions on the non-linearity. They typically cannot be checked in practice but do link convergence to simple, empirical, gain selection rules.

ILC, as a topic, is a large area of study. Literature surveys indicate an increasing number of applications and also that progress has been made in a number of design areas including adaptive ILC, the use of intelligent control ideas, 2D systems theory and mathematical studies of fractional order control laws (Chen et al. 2013). The further development of ILC from its current

strong base will draw extensively from classical control knowledge but relies on the three aspects of *plant modelling*, *control design* and *coping with uncertainty*. Issues central to success include:

1. Extending current ILC knowledge to other classes of model needed for applications.
2. Integration of online data-based modelling into ILC schemes to enhance adaptive control options.
3. Ensuring the property of error monotonicity or characterizing any expected non-monotonicity.
4. The construction of robustness tests and using the ideas in new robust design methodologies.
5. Providing a better understanding of the effect of noise and disturbances on algorithm performance.
6. Extending the range of tasks to include, for example, different challenges for different outputs on different subintervals of $[0, T]$ (Owens 2016).
7. Creating design tools for non-linear plant that ensure convergence and a degree of robustness but, in particular, provide some control of internal plant states that may be subject to dynamical constraints.

Kalman Filters

Frederick E. Daum
Raytheon Company, Woburn, MA, USA

Abstract

The Kalman filter is a very useful algorithm for linear Gaussian estimation problems. It is extremely popular and robust in practical applications. The algorithm is easy to code and test. There are many reasons for the popularity of the Kalman filter in the real world, including stability and generality and simplicity. Moreover, the real-time computational complexity is very reasonable for high-dimensional problems. In particular, the computational complexity scales as the cube of the dimension of the state vector.

Description of Kalman Filter

The Kalman filter is an algorithm that computes the best estimate of the state vector of a linear dynamical system given discrete time measurements of a linear function of the state vector corrupted by additive white Gaussian noise. The Kalman filter also quantifies the uncertainty in its estimate of the state vector, using the covariance matrix of estimation errors. The detailed equations of the Kalman filter algorithm and the problem that it solves are given in Gelb et al. (1974), which is the most accessible but thorough book on Kalman filters. The linear dynamical system can be time varying, but its parameters must be known exactly. The measurements can be made at arbitrary (nonuniform) discrete times, but these times must be known exactly. Likewise, the covariance matrices of the measurement errors and the process noise can be arbitrary and time varying, but the numerical values of these covariance matrices must be known exactly. Also, the initial uncertainty in the state vector must be Gaussian and the mean and covariance matrix can be arbitrary, but these must be known exactly. There is a very powerful theory of Kalman filter stability due to Kalman (1961), which guarantees that the Kalman filter is stable under very mild

technical assumptions which can always be satisfied in practice. In particular, the Kalman filter is stable for estimating the state vector of linear dynamical systems that are stable or unstable, for arbitrarily slow measurement rates, provided that the mild technical assumptions are fulfilled. These assumptions require that the dimension of the state vector is minimal and that the measurement error covariance matrix and the process noise covariance matrices are positive definite, although weaker conditions are also sufficient for stability in some cases; see Kailath et al. (2000) for such details on the stability of the Kalman filter. Kalman filter stability is connected with observability and controllability of the input-output model of the relevant dynamical system in Kalman (1961). The corresponding algorithm for continuous time linear measurements (with Gaussian additive white noise) and continuous time linear dynamical systems (with Gaussian additive white process noise) is called the Kalman-Bucy filter; see Kalman (1961).

Design Issues

In engineering practice, almost all real-world applications are nonlinear or non-Gaussian, and therefore, they do not fit the Kalman filter theory. Nevertheless, by approximating the nonlinear dynamics and measurements with linear equations, one can apply the Kalman filter theory; this is called the “extended Kalman filter” (EKF); see Gelb et al. (1974). The linearization of the nonlinear dynamics and measurements is made by computing the first-order Taylor series expansion and evaluating it at the estimated state vector; this is a very simple and fast approximation that is widely used in real-world applications, and it often gives good estimation accuracy, although there is no guarantee of that. Moreover, there is no guarantee that the EKF will be stable, even if the linearized system satisfies all the theoretical requirements for stability of the Kalman filter.

Even if the dynamics and measurements are exactly linear and if the measurement noise and process noise and initial uncertainty

are all exactly Gaussian with exactly known means and covariance matrices, there can still be significant practical problems with Kalman filter accuracy, owing to ill-conditioning. In particular, the Kalman filter can be extremely sensitive to quantization errors in the computer arithmetic and storage. On the other hand, there are many different methods to try to mitigate ill-conditioning including (1) double or quadruple or octuple precision arithmetic, (2) making the covariance matrices symmetric before and after every operation, (3) Tychonov regularization, (4) tuning the process noise covariance matrix, (5) coding the Kalman filter in principal coordinates or approximately principal coordinates (i.e., aligned with the eigenvectors of the state vector error covariance matrix), (6) sequential scalar measurement updates in a preferred order, and (7) various factorizations of the covariance matrices (e.g., square root, information matrix, information square root, upper triangular and lower triangular factorization, UDL, etc.). The classic book on error covariance matrix factorizations is by Bierman (2006). Unfortunately, there is no guarantee that the Kalman filter will work well even if all of these mitigation methods are used. Moreover, there is no useful theoretical analysis of this phenomenon, with the exception of a few not very tight upper bounds on the condition number. Plotting the numerical values of the condition number of the covariance matrix vs. time is often a helpful diagnostic. In certain real-world applications, the condition number of the Kalman filter error covariance matrix can be ten billion or larger.

Why Is the Kalman Filter So Useful and Popular?

The Kalman filter has been enormously successful in real-world applications, and it is interesting to reflect on why it has been so useful and so popular. In particular, Kalman himself believed that his filter was successful because it was based on probability rather than statistics; see Kalman (1978). For example, the error covariance matrix for the Kalman filter is computed

from the assumed dynamics and measurement model and the assumed values of the initial state uncertainty and process noise and measurement noise covariance matrices, rather than by computing sample covariance matrices. Likewise, the Kalman filter computes the estimated state vector from assumed Gaussian and linear probability models, rather than computing the sample mean, as would be done in statistics. There is substantial wisdom in Kalman's assertion, owing to the difficulty of estimating sample covariance matrices and sample vectors that are sufficiently accurate, given a limited number of samples and ill-conditioning and high-dimensional state vectors. A second reason that Kalman filters are so popular is that the real-time computational complexity is very reasonable for modern digital computers, even for problems with a high-dimensional state vector. In particular, the computational complexity of the Kalman filter scales as the cube of the dimension of the state vector; for example, the modern GPS system uses a Kalman filter with a state vector of dimension of about 1,000 to jointly estimate the orbits of the satellites in the GPS constellation. In 1960, when Kalman's paper was first published, digital computers were starting to become fast enough at reasonable cost to multiply large matrices in real time, which is the most challenging computation in a Kalman filter. Today computers are roughly ten orders of magnitude faster per unit cost than in 1960, and hence, we can run Kalman filters for high-dimensional problems on very inexpensive computers that fit into your wristwatch. A third reason that Kalman filters are popular is that the algorithms are easy to understand and code and test. A fourth reason is the guaranteed stability of the Kalman filter under very mild conditions which can always be satisfied in practical applications. A fifth reason is that the Kalman filter is optimal for time-varying unstable linear dynamics with time-varying measurement noise covariance and process noise covariance. A sixth reason is that one can use Kalman filters for nonlinear problems by approximating the nonlinear dynamics and measurement equations with a first-order Taylor series; this is called the extended Kalman filter (EKF), which is without

a doubt the most widely used algorithm in real-world estimation applications. A seventh reason is that the Kalman filter automatically provides a convenient quantification of uncertainty of the estimated state vector using the error covariance matrix. The final reason is that it is easy to test the accuracy of the Kalman filter by comparing the theoretical error covariance matrix to errors computed by Monte Carlo simulations of the filter; the two errors should agree approximately, and statistically significant discrepancies suggest bugs in the code or ill-conditioning of the error covariance matrices or nonlinearities or errors in modeling the dynamics or measurements.

Kalman's 1960 paper represented a big paradigm shift in two ways: (1) it exploited fast low-cost modern digital computers, whereas the literature up to that time did not, and (2) it used time domain methods rather than the ubiquitous Fourier transform methods, which limited the dynamics to steady state asymptotic in time, which in turn limited the theory to cover stable dynamics. Of course today we take both of these big points as normal engineering rather than revolutionary and surprising. The state of the art prior to Kalman's 1960 paper was the Wiener filter, which was based firmly on the Fourier transform. The Wiener filter required very lengthy and cumbersome algebraic spectral factorization with complex variables, resulting in erroneous formulas published in certain books, owing to algebraic errors which were not obvious and which could not be checked by computers, owing to the nonexistence of computer algebra software (e.g., MATHEMATICA) in 1960. Kalman explains many other problems with the Wiener filter in Kalman (2003).

Summary and Future Directions

To a large extent the Kalman filter theory is complete. There is a simple and useful theory of stability of the Kalman filter, which is completely lacking for nonlinear filters including the extended Kalman filter (EKF) and particle filters. Moreover, there are many robust versions of the Kalman filter that have been invented to

mitigate ill-conditioning of the covariance matrix as well as uncertainty in system models and system parameters. However, there remain many important design issues that need to be addressed for practical applications; see Daum (2005) for details. The most obvious issues include nonlinear measurements, nonlinear plant models, robustness to uncertainty in measurement models and plant models, non-Gaussian measurement noise and plant noise, non-Gaussian initial uncertainty in the state vector, and ill-conditioning of the error covariance matrix. That is, any deviation from the exact mathematical assumptions in the Kalman filter theory can cause problems in practice. It is the job of engineers to mitigate such problems and design filters that are robust to such perturbations. Kalman's recent papers on how the Kalman filter was invented and why it is so popular contain interesting and useful ideas; see Kalman (1978) and Kalman (2003).

KYP Lemma and Generalizations/Applications

Tetsuya Iwasaki

Department of Mechanical and Aerospace Engineering, University of California, Los Angeles, CA, USA

Abstract

Various properties of dynamical systems can be characterized in terms of inequality conditions on their frequency responses. The Kalman-Yakubovich-Popov (KYP) lemma shows equivalence of such frequency domain inequality (FDI) and a linear matrix inequality (LMI). The fundamental result has been a basis for robust and optimal control theories in the past several decades. The KYP lemma has recently been generalized to the case where an FDI on a possibly improper transfer function is required to hold in a (semi)finite frequency range. The generalized KYP lemma allows us to directly deal with practical situations where design parameters are sought to satisfy FDIs in multiple (semi)finite frequency ranges. Various design problems, including FIR filter and PID controller, reduce to LMI problems which can be solved via semidefinite programming.

Positive real · Robust control

Introduction

In linear systems analysis and control design, dynamical properties are often characterized by frequency responses. The shape of a frequency response, as visualized by the Bode or Nyquist plot, is closely related to various performance measures including the steady state error, fast and smooth transient, and robustness against unmodeled dynamics. Hence, desired system properties can be formalized in terms of a set of frequency domain inequalities (FDIs) on selected transfer functions. The analysis and design problems then reduce to verification and satisfaction of the FDIs.

The Kalman-Yakubovich-Popov (KYP) lemma (Kalman 1963; Anderson 1967; Willems 1971; Rantzer 1996) establishes the equivalence between an FDI and a linear matrix inequality (LMI). The LMI is defined by state space matrices of the transfer function in the FDI so that the FDI holds true if and only if the LMI admits a solution. The LMI characterization of an FDI is useful since it replaces the process of checking the FDI at infinitely many frequency points by the search for a symmetric matrix satisfying a finite dimensional convex constraint defined by the LMI. In addition to exact and tractable computations, benefits of the LMI conditions include analytical understanding of robust and optimal controls through spectral factorizations and storage/Lyapunov functions. The KYP lemma is a fundamental result in the systems and control field that has provided, in the past half century, a theoretical basis for developments of various tools for system analysis and design.

A drawback of the KYP lemma is its inability to characterize an FDI in a finite frequency range. Feedback control designs typically involve a set of specifications given in terms of multiple FDIs in various frequency ranges. However, the KYP lemma is not capable of treating such FDIs directly since it has to consider the entire

frequency range. To address this deficiency, the KYP lemma has recently been generalized to characterize an FDI in a finite frequency range exactly (Iwasaki et al. 2000). Further generalizations (Iwasaki and Hara 2005) are available for FDIs within various frequency ranges for both continuous- and discrete-time, possibly improper, rational transfer functions. The generalized KYP lemma allows for direct multi-objective design of filters, controllers, and dynamical systems.

KYP Lemma

The KYP lemma may be motivated from various aspects, but let us explain it as an extension of a gain condition. Consider a stable linear system

$$\dot{x} = Ax + Bu, \quad G(s) := (sI - A)^{-1}B,$$

where $x(t) \in \mathbb{R}^n$ is the state, $u(t) \in \mathbb{R}^m$ is the input, and $G(s)$ is the transfer function from u to x . If u is a disturbance to the system and x represents the error from a desired operating point, we may be interested in how large the state variables can become for a given magnitude of the disturbance. The gain $\|G(j\omega)\|$ captures this property for the case of a sinusoidal disturbance at frequency ω , where $\|\cdot\|$ denotes the spectral norm (= absolute value for a scalar). If $\|G(j\omega)\| < \gamma$ holds for all frequency ω with a small γ , then the system has a good disturbance attenuation property.

A version of the KYP lemma states that the FDI $\|G(j\omega)\| < \gamma$ with $\gamma = 1$ holds for all frequency ω if and only if there exists a symmetric matrix P satisfying the LMI:

$$\begin{bmatrix} PA + A^T P + I & PB \\ B^T P & -I \end{bmatrix} < 0.$$

Thus, existence of one particular P satisfying the LMI is enough to conclude that the gain is less than one for all, infinitely many, frequencies. This result is known as the bounded real lemma and has played a fundamental role in the robust and H_∞ control theories.

The KYP lemma can be introduced as a generalization of the bounded real lemma. First, note that the gain bound condition $\|G(j\omega)\| < 1$ and the LMI condition can equivalently be written as

$$\begin{bmatrix} G(j\omega) \\ I \end{bmatrix}^* \Theta \begin{bmatrix} G(j\omega) \\ I \end{bmatrix} < 0, \quad (1)$$

$$\begin{bmatrix} PA + A^T P & PB \\ B^T P & 0 \end{bmatrix} + \Theta < 0, \quad (2)$$

where

$$\Theta := \begin{bmatrix} I & 0 \\ 0 & -I \end{bmatrix}.$$

In these equations, the particular matrix Θ is chosen to describe the gain bound condition as a special case of the quadratic form (1), and we observe that Θ appears in the LMI as in (2). It turns out that the equivalence of (1) and (2) holds not only for this particular Θ but also for an arbitrary symmetric matrix Θ . This result is called the KYP lemma, which states that, given arbitrary matrices A , B , and $\Theta = \Theta^T$, the FDI (1) holds for all frequency ω if and only if there exists a matrix $P = P^T$ satisfying the LMI (2), provided A has no eigenvalues on the imaginary axis.

The FDI in (1) can be specialized to an FDI

$$\begin{bmatrix} L(j\omega) \\ I \end{bmatrix}^* \Pi \begin{bmatrix} L(j\omega) \\ I \end{bmatrix} < 0. \quad (3)$$

on transfer function

$$L(s) := C(sI - A)^{-1}B + D$$

by choosing

$$\Theta := \begin{bmatrix} C & D \\ 0 & I \end{bmatrix}^T \Pi \begin{bmatrix} C & D \\ 0 & I \end{bmatrix}. \quad (4)$$

The choice of matrix Π allows for characterizations of important system properties involving gain and phase of $L(s)$. For instance, the FDI (3) with

$$\Pi := \begin{bmatrix} 0 & -I \\ -I & 0 \end{bmatrix}$$

gives $L(j\omega) + L(j\omega)^* > 0$. This is called the positive real property, with which the phase angle remains between $\pm 90^\circ$ when $L(j\omega)$ is a scalar.

Generalization

The standard KYP lemma deals with FDIs that are required to hold for all frequencies. To allow for more flexibility in practical system designs, the KYP lemma has been generalized to deal with FDIs in (semi)finite frequency ranges.

For instance, a version of the generalized KYP lemma states that the FDI (1) holds in the low frequency range $|\omega| \leq \varpi_\ell$ if and only if there exist matrices $P = P^T$ and $Q = Q^T > 0$ satisfying

$$\begin{bmatrix} A & B \\ I & 0 \end{bmatrix}^T \begin{bmatrix} -Q & P \\ P & \varpi_\ell^2 Q \end{bmatrix} \begin{bmatrix} A & B \\ I & 0 \end{bmatrix} + \Theta < 0, \quad (5)$$

provided A has no imaginary eigenvalues in the frequency range. In the limiting case where ϖ_ℓ approaches infinity and the FDI is required to hold for the entire frequency range, the solution Q to (5) approaches zero, and we recover (2).

The role of the additional parameter Q is to enforce the FDI only in the low frequency range. To see this, consider the case where the system is stable and a sinusoidal input $u = \Re[\hat{u}e^{j\omega t}]$, with (complex) phasor vector $\hat{u}$, is applied. The state converges to the sinusoid $x = \Re[\hat{x}e^{j\omega t}]$ in the steady state where $\hat{x} := G(j\omega)\hat{u}$. Multiplying (5) by the column vector obtained by stacking $\hat{x}$ and $\hat{u}$ in a column from the right, and by its complex conjugate transpose from the left, we obtain

$$(\varpi_\ell^2 - \omega^2)\hat{x}^* Q \hat{x} + \begin{bmatrix} \hat{x} \\ \hat{u} \end{bmatrix}^* \Theta \begin{bmatrix} \hat{x} \\ \hat{u} \end{bmatrix} < 0.$$

In the low frequency range $|\omega| \leq \varpi_\ell$, the first term is nonnegative, enforcing the second term to be negative, which is exactly the FDI in (1). If ω is outside of the range, however, the first term is negative, and the FDI is not required to hold.

Similar results hold for various frequency ranges. The term involving Q in (5) can be expressed as the Kronecker product $\Psi \otimes Q$ with Ψ being a diagonal matrix with entries $(-1, \varpi_\ell^2)$. The matrix Ψ arises from characterization of the low frequency range:

$$\begin{bmatrix} j\omega \\ 1 \end{bmatrix}^* \Psi \begin{bmatrix} j\omega \\ 1 \end{bmatrix} = \varpi_\ell^2 - \omega^2 \geq 0.$$

By different choices of Ψ , middle and high frequency ranges can also be characterized:

	Low	Middle	High
Ω	$ \omega \leq \varpi_\ell$	$\varpi_1 \leq \omega \leq \varpi_2$	$ \omega \geq \varpi_h$
Ψ	$\begin{bmatrix} -1 & 0 \\ 0 & \varpi_\ell^2 \end{bmatrix}$	$\begin{bmatrix} -1 & j\varpi_c \\ -j\varpi_c & -\varpi_1\varpi_2 \end{bmatrix}$	$\begin{bmatrix} 1 & 0 \\ 0 & -\varpi_h^2 \end{bmatrix}$

where $\varpi_c := (\varpi_1 + \varpi_2)/2$ and Ω is the frequency range. For each pair (Ω, Ψ) , the FDI (1) holds in the frequency range $\omega \in \Omega$ if and only if there exist real symmetric matrices P and $Q > 0$ satisfying

$$F^T(\Phi \otimes P + \Psi \otimes Q)F + \Theta < 0, \quad (6)$$

provided A has no eigenvalues in Ω , where

$$\Phi := \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad F := \begin{bmatrix} A & B \\ I & 0 \end{bmatrix}.$$

Further generalizations are available Iwasaki and Hara (2005). The discrete-time case (frequency variable on the unit circle) can be similarly treated by a different choice of Φ . FDIs for descriptor systems and polynomial (rather than rational) functions can also be characterized in a form similar to (6) by modifying the matrix F . More specifically, the choices

$$\Phi := \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}, \quad F := \begin{bmatrix} A & B \\ E & O \end{bmatrix}$$

give the result for the discrete-time transfer function $L(z) = (zE - A)^{-1}(B - zO)$.

Applications

The generalized KYP lemma is useful for a variety of dynamical system designs. As an example, let us consider a classical feedback control design via shaping of a scalar open-loop transfer function in the frequency domain. The objective is to design a controller $K(s)$ for a given plant $P(s)$ such that the closed-loop system is stable and possesses a good performance dictated by reference tracking, disturbance attenuation, noise sensitivity, and robustness against uncertainties.

Typical design specifications are given in terms of bounds on the gain and phase of the open-loop transfer function $L(s) := P(s)K(s)$ in various frequency ranges as shown in Fig. 1. The controller $K(s)$ should be designed so that the frequency response $L(j\omega)$ avoids the shaded regions. For instance, the gain should satisfy $|L(j\omega)| \geq 1$ for $|\omega| < \omega_2$ and $|L(j\omega)| \leq 1$ for $|\omega| > \omega_3$ to ensure the gain crossover occurs in the range $\omega_2 \leq \omega \leq \omega_3$, and the phase bound $\angle L(j\omega) \geq \theta$ in this range ensures robust stability by the phase margin.

KYP Lemma and Generalizations/Applications, Fig. 1
Loop shaping design specifications

The design specifications can be expressed as FDIs of the form (3), where a particular gain or phase condition can be specified by setting Π as

$$\pm \begin{bmatrix} 1 & 0 \\ 0 & -\gamma^2 \end{bmatrix} \quad \text{or} \quad \begin{bmatrix} 0 & j - \tan \theta \\ -j - \tan \theta & 0 \end{bmatrix}$$

with $\gamma = \gamma_1, \gamma_4$, or 1, and the $+/-$ signs for upper/lower gain bounds. These FDIs in the corresponding frequency ranges can be converted to inequalities of the form (6) with Θ given by (4).

The control problem is now reduced to the search for design parameters satisfying the set of inequality conditions (6). In general, both coefficient matrices F and Θ may depend on the design parameters, but if the poles of the controller are fixed (as in the PID control), then the design parameters will appear only in Θ . If in addition an FDI specifies a convex region for $L(j\omega)$ on the complex plane, then the corresponding inequality (6) gives a convex constraint on P, Q , and the design parameters. This is the case for specifications of gain upper bound (disk: $|L| < \gamma$) and phase bound (half plane: $\theta \leq \angle L \leq \theta + \pi$). A gain lower bound $|L| > \gamma$ is not convex but can often be approximated by a half plane. The design parameters satisfying the specifications can then be computed via convex programming.

Various design problems other than the open-loop shaping can also be solved in a similar manner, including finite impulse response (FIR) digital filter design with gain and phase constraints in a passband and stop-band and sensor or actuator placement for mechanical control systems (Hara et al. 2006; Iwasaki et al. 2003). Control design with the Youla parametrization also falls within the framework if a basis expansion is used for the Youla parameter and the coefficients are sought to satisfy convex constraints on closed-loop transfer functions.

are expressed in terms of state space matrices without involving the frequency variable. The resulting LMI condition has been found useful for developing robust and optimal control theories.

A recent generalization of the KYP lemma characterizes an FDI for a possibly improper rational function in a (semi)finite frequency range. The result allows for direct solutions of practical design problems to satisfy multiple specifications in various frequency ranges. A design problem is essentially solvable when transfer functions are affine in the design parameters and are required to satisfy convex FDI constraints. An important problem, which falls outside of this framework and remains open, is the design of feedback controllers to satisfy multiple FDIs on closed-loop transfer functions in various frequency ranges. There have been some attempts to address this problem, but none of them has so far succeeded to give an exact solution.

The KYP lemma has been extended in other directions as well, including FDIs with frequency-dependent weights (Graham and de Oliveira 2010), internally positive systems (Tanaka and Langbort 2011), full rank polynomials (Ebihara et al. 2008), real multipliers (Pipeleers and Vandenberghe 2011), a more general class of FDIs (Gusev 2009), multi-dimensional systems (Bachelier et al. 2008), negative imaginary systems (Xiong et al. 2012), symmetric formulations for robust stability analysis (Tanaka and Langbort 2013), and multiple frequency intervals (Pipeleers et al. 2013). Extensions of the KYP lemma and related S-procedures are thoroughly reviewed in Gusev and Likhtarnikov (2006). A comprehensive tutorial of robust LMI relaxations is provided in Scherer (2006) where variations of the KYP lemma, including the generalized KYP lemma as a special case, are discussed in detail.

Summary and Further Directions

The KYP lemma has played a fundamental role in systems and control theories, equivalently converting an FDI to an LMI. Dynamical systems properties characterized in the frequency domain

Abstract

An approach to feedback controller synthesis involves minimizing a uniform across time bound for the size of a controlled output, given a bound of the same kind for the disturbance input. In the case of linear time-invariant dynamics, this corresponds to minimizing the ℓ_1 norm of the closed-loop impulse response. This optimal control problem can be recast exactly as a finite-dimensional linear program for single-input-single-output systems. On the other hand, for multiple-input-multiple-output systems, the optimal control problem can be approximated to arbitrary accuracy by a linear program of size that grows as the accuracy is improved. An overview of these results is provided in the entry below.

Keywords

Feedback control · Bounded signals · Linear time-invariant systems · Youla parametrization · Linear programming

Glossary

- ℓ_1 Space of right-sided absolutely summable real sequences with the norm given by $\|x\|_{\ell_1} = \sum_{k=0}^{\infty} |x(k)|$
- $\hat{x}(\lambda)$ λ -Transform of a right-sided real sequence $x = (x(k))_{k=0}^{\infty}$ defined as $\hat{x}(\lambda) = \sum_{k=0}^{\infty} x(k)\lambda^k$.
- P_N Truncation operator for sequences defined as $P_N \begin{pmatrix} x(0) & x(1) & \dots \end{pmatrix} = \begin{pmatrix} x(0) & x(1) & \dots & x(N-1) & 0 & \dots \end{pmatrix}$

Introduction: The ℓ_1 Norm

Feedback control effectively reduces the impact of uncertainty; indeed, apart from stabilizing unstable systems, minimizing the adverse effects of uncertainty is its primary goal. In any control system design where mathematical descriptions of signals and system is assumed, the models can only approximate the reality where the description is incomplete or its complexity makes its incorporation in controller synthesis ineffective.

In modern control design, uncertainty is classified into two classes: (i) signal uncertainty and (ii) model uncertainty. Signal uncertainty is caused by an incomplete knowledge of the inputs affecting the system; for example, for an aircraft, there is scant or incomplete information

on the direction and strength of the wind that affects its motion. However, it is often possible to provide bounds that encapsulate the knowledge of the external inputs, whereby these exogenous influences can be restricted to a set. Various measures can be employed in characterizing the inputs. A widely used measure in a probabilistic setting is the variance of the input modeled as white noise. In a deterministic description, the energy, $\|\cdot\|_{\ell_2}$, and the maximum magnitude, $\|\cdot\|_{\ell_\infty}$ of the signal are often employed. The ℓ_∞ norm and the ℓ_2 norms are defined as

$$\|w\|_{\ell_\infty} := \sup_{0 \leq t < \infty} |w(t)| \text{ and}$$

$$\|w\|_{\ell_2} := \sqrt{\sum_{t=0}^{\infty} |w(t)|^2},$$

respectively, for a discrete time scalar signal w . For a vector valued signal w with $w(t) \in R^d$ the norms are defined as

$$\|w\|_{\ell_\infty} := \max_{1 \leq i \leq d} \sup_{0 \leq t < \infty} |w_i(t)| \text{ and } \|w\|_{\ell_2}$$

$$:= \sqrt{\sum_{t=0}^{\infty} \sum_{i=1}^d |w_i(t)|^2}.$$

For the purposes here, the exogenous input to the system is restricted to lie in a set $\mathcal{W} = \{w : \|w\|_{\ell_\infty} \leq M\}$.

To quantify the performance of a system, apart from using a norm for inputs, it is essential to employ measures on outputs. In many applications, outputs are constrained from exceeding a magnitude bound. For example, tracking errors need to remain within limits in many application where reference trajectories are to be followed over time and in many applications actuators and safety concerns necessitate signals do not cross imposed limits (e.g., in power applications voltage signals need to be within acceptable bounds). Here, the ℓ_∞ norm is an apt measure to quantify the output signals.

ℓ_1 optimal control is pertinent to the case where the input and output signals are quantified using the ℓ_∞ norm of the signals, where the

input is considered to lie in a set $\mathcal{W} = \{w : \|w\|_{\ell_\infty} \leq 1\}$. Here we restrict our study to linear, time-invariant (LTI) causal discrete time systems; systems will be denoted using boldface symbols. Thus if a LTI system, $\mathbf{T}$, maps a input signal, $w(\cdot)$, to yield an output signal, $e(\cdot) = (\mathbf{T}w)(\cdot)$, where the impulse response of the system $\mathbf{T}$ is T , then the output, $e = \mathbf{T}w$, satisfies $(\mathbf{T}w)(t) = (T * w)(t)$ (or $\hat{e} = \hat{T}\hat{w}$) where $*$ denotes convolution operator between signals and $\hat{T}$, the transfer function map, is the λ -Transform of T . A possible quantification of the system performance is the worst possible output (evaluated using the ℓ_∞ norm) over any input from the admissible class $\mathcal{W}$. Thus,

$$\sup_{w \in \mathcal{W}} \frac{\|(\mathbf{T}w)(\cdot)\|_{\ell_\infty}}{\|w\|_{\ell_\infty}},$$

which considers the worst-case amplification of a input signal, provides a quantification of the performance of the system $\mathbf{T}$. Note that the above measure on the system $\mathbf{T}$ is the ℓ_∞ induced norm of the system $\mathbf{T}$.

The ℓ_1 norm of a scalar signal, h , is given by

$$\|h\|_{\ell_1} = \sum_{t=0}^{\infty} |h(t)|.$$

Suppose for a linear system, the exogenous input w is n_w -dimensional and the regulated output is n_z -dimensional. Let the response of the i th output of the system, with the j th input being an impulse, be $T_{ij}(\cdot)$. Then the ℓ_1 norm of the multiple-input-multiple-output system $\mathbf{T}$ is defined as

$$\|\mathbf{T}\|_{\ell_1} = \max_{1 \leq i \leq n_z} \sum_{j=1}^{n_w} \|T_{ij}\|_{\ell_1}.$$

The following result shows how the ℓ_∞ induced norm of the system $\mathbf{T}$ is related to the ℓ_1 norm of the impulse response, T , of the system.

Theorem 1

$$\sup_{w \in \mathcal{W}} \frac{\|(\mathbf{T}w)(\cdot)\|_{\ell_\infty}}{\|w(\cdot)\|_{\ell_\infty}} = \|\mathbf{T}\|_{\ell_1}.$$

Note that for a single-input-single-output system the ℓ_1 norm of the system is the absolute sum $\sum_{t=0}^{\infty} |h(t)|$ of the impulse response, h , of the system. The above result motivates the ℓ_1 norm for controller synthesis.

Control Synthesis

Consider a system, $\mathbf{G}$, with external input, w , that affect the outputs, the control input u with measured outputs y and output, z , to be regulated. The measurements are used by the controller to produce the control signal u . Figure 1a describes the generalized plant G . Here

$$\begin{pmatrix} z \\ y \end{pmatrix} = \underbrace{\begin{pmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{pmatrix}}_G * \begin{pmatrix} w \\ u \end{pmatrix}, \text{ with } u = K * y$$

where G and K are the impulse responses of $\mathbf{G}$ and the controller $\mathbf{K}$. Here, $z = G_{11} * w + G_{12} * u$ and $y = G_{21} * w + G_{22} * u$. Substituting $u = K * y$, the closed-loop system, $F_\ell(\mathbf{G}, \mathbf{K})$, is obtained as

$$\hat{z} = \underbrace{[\hat{G}_{11} + \hat{G}_{12} \hat{K} (I - \hat{G}_{22} \hat{K})^{-1} \hat{G}_{21}]}_{\hat{F}_\ell(\hat{G}, \hat{K})} \hat{w}.$$

It is important that only closed-loop maps that result via controllers that stabilize the interconnection in Fig. 1a be considered.

Definition 2 (Stabilizing controllers, Achievable closed-loop maps) A controller $\mathbf{K}$ which results in a stable interconnection of $\mathbf{G}$ and $\mathbf{K}$ systems represented in Fig. 1a is a stabilizing controller. A transfer function, $\hat{\Phi}$, that maps the exogenous inputs $\hat{w}$ to regulated variables

$\hat{z}$ is said to be an achievable closed-loop map if there exists a stabilizing controller $\mathbf{K}$ such that $\hat{\Phi} = \hat{G}_{11} + \hat{G}_{12} \hat{K} (I - \hat{G}_{22} \hat{K})^{-1} \hat{G}_{21}$.

The ℓ_1 optimal controller synthesis problem is to determine a stabilizing controller $\mathbf{K}$ where the worst-case response of the closed-loop system over all signals in $\mathcal{W}$ is minimized. Thus the ℓ_1 controller synthesis problem is given by

$$\begin{aligned} v &= \inf_{\mathbf{K} \text{ stabilizing}} \sup_{w \in \mathcal{W}} \frac{\|F_\ell(\mathbf{G}, \mathbf{K})w\|_{\ell_\infty}}{\|w\|_{\ell_\infty}} \\ &= \inf_{\mathbf{K} \text{ stabilizing}} \|F_\ell(G, K)\|_{\ell_1} \end{aligned} \quad (1)$$

where $F_\ell(G, K)$ is the impulse response of the closed-loop map from w to z . The following example is illustrative of the discussion thus far.

Example

Consider the problem described in Fig. 2a where a plant $\mathbf{P}$ is subjected to a input disturbance modeled as filtered signal $\mathbf{W}w$, where $\mathbf{W}$ models the frequency content of the disturbance and $w \in \mathcal{W} = \{v : \|v\|_\infty \leq 1\}$. The generalized plant is described as

$$\begin{pmatrix} \hat{z} \\ \hat{y} \end{pmatrix} = \underbrace{\begin{pmatrix} \hat{P}\hat{W} & -\hat{P} \\ \hat{P}\hat{W} & -\hat{P} \end{pmatrix}}_{\hat{G}} \begin{pmatrix} \hat{w} \\ \hat{u} \end{pmatrix},$$

with $\hat{G}_{11} = \hat{G}_{21} = \hat{P}\hat{W}$ and $\hat{G}_{12} = \hat{G}_{22} = -\hat{P}$. The closed-loop map from w to z has a transfer function

$$\begin{aligned} \hat{F}_\ell(\hat{G}, \hat{K}) &= \hat{G}_{11} + \hat{G}_{12} \hat{K} (I - \hat{G}_{22} \hat{K})^{-1} \hat{G}_{21} \\ &= \hat{P}\hat{W} - \hat{P}\hat{K} (1 + \hat{P}\hat{K})^{-1} \hat{P}\hat{W}. \end{aligned}$$

L1 Optimal Control,

Fig. 1 (a) shows a generalized plant $\mathbf{G}$ in a feedback interconnection with the controller $\mathbf{K}$. (b) shows the closed-loop system, $F_\ell(\mathbf{G}, \mathbf{K})$ which maps exogenous inputs to regulated output z

L1 Optimal Control, Fig. 2 (a) shows a plant P subject to input disturbance modeled as a magnitude constrained signal w filtered by W . (b) shows the interconnection between G , K , and Δ . The unstructured uncertainty Δ is

characterized by $\|\Delta\|_{\ell_1} < \frac{1}{\gamma}$. To maintain stability, a hard constraint that the closed-loop map from w_1 to z_1 should be less than γ is imposed

Thus the ℓ_1 optimal controller synthesis problem translates to solving,

$$\nu = \inf_{\mathbf{K} \text{ stabilizing}} \|\hat{P}\hat{W} - \hat{P}\hat{K}(1 + \hat{P}\hat{K})^{-1}\hat{P}\hat{W}\|_{\ell_1}.$$

It is evident that the ℓ_1 optimal controller synthesis problem is non-convex in the optimization variable $\mathbf{K}$ as posed in (1).

Solution Methodologies

The solution approaches to the ℓ_1 optimal controller synthesis problem have to address the following two challenges: (i) the non-convexity of the optimization problem (1) in the argument $\mathbf{K}$ that needs to be stabilizing and (ii) the possible infinite dimensional nature of the optimization problem. To address the non-convexity, Youla parametrization is employed.

Youla parameterization (see Youla et al. (1976) and related articles Optimal Control via Factorization and Model Matching and Polynomial/algebraic design methods in this encyclopedia) translates the search over stabilizing controllers to search over Q parameters where the closed-loop map is convex in Q .

Theorem 3 (Youla Parametrization) Let G be stabilizable from u and detectable from y . Let $\hat{G}$

be the transfer-function map with

$$\begin{pmatrix} \hat{z} \\ \hat{y} \end{pmatrix} = \underbrace{\begin{pmatrix} \hat{G}_{11} & \hat{G}_{12} \\ \hat{G}_{21} & \hat{G}_{22} \end{pmatrix}}_{\hat{G}} \begin{pmatrix} \hat{w} \\ \hat{u} \end{pmatrix}.$$

Suppose $\hat{G}_{22}$ admits a double co-prime factorization where

$$G_{22} = \hat{N}\hat{M}^{-1} = \hat{\tilde{M}}^{-1}\hat{\tilde{N}},$$

with

$$\begin{pmatrix} \hat{\tilde{X}} & -\hat{\tilde{Y}} \\ -\hat{\tilde{N}} & \hat{\tilde{M}} \end{pmatrix} \begin{pmatrix} \hat{M} & \hat{Y} \\ \hat{N} & \hat{X} \end{pmatrix} = I,$$

and $\tilde{X}, \tilde{Y}, \tilde{M}, \tilde{N}, X, Y, M, N$ have finite ℓ_1 norms.

Then, $\hat{\Phi}$ is a closed-loop map with $\hat{\Phi} = \hat{G}_{11} + \hat{G}_{12}\hat{K}(I - \hat{G}_{22}\hat{K})^{-1}\hat{G}_{21}$ for a stabilizing controller $\mathbf{K}$ if and only if

$$\hat{\Phi} \in \{\hat{H} - \hat{U}\hat{Q}\hat{V} : Q \in \ell_1\}$$

where $\hat{H} = \hat{G}_{11} + \hat{G}_{12}\hat{Y}\hat{M}\hat{G}_{21}$, $\hat{U} = \hat{G}_{12}\hat{M}$ and $\hat{V} = \hat{\tilde{M}}$.

Using Youla Parameterization, the ℓ_1 optimal control problem can be recast in terms of the Youla parameter Q .

Theorem 4 *The following holds:*

$$v = \inf_{\hat{K}, \Phi} \{ \|\Phi\|_{\ell_1} : \hat{K} \text{ stabilizing}, \hat{\Phi} = \hat{G}_{11} + \hat{G}_{12} \hat{K} (I - \hat{G}_{22} \hat{K})^{-1} \hat{G}_{21} \} \quad (2)$$

$$= \inf_{Q \in \ell_1, \Phi \in \ell_1} \{ \|\Phi\|_{\ell_1} : \Phi = H - U * Q * V \}. \quad (3)$$

Note that (3) is convex in the optimization variables Φ and Q ; however, possibly infinite-dimensional in the impulse response parameters of Q and Φ . One of the earliest approaches taken is to eliminate the variable Q from the optimization in (3) and to recast the problem retaining only the closed-loop variable Φ . This approach is elucidated for the SISO setting in what follows.

SISO Case

Theorem 5 *Consider the SISO case with $n_w = n_z = 1$. Suppose Youla Parameterization yields that Φ is achievable closed-loop map via a stabilizing controller if and only if $\Phi = H - U * Q$ (as the system is SISO, V of the Youla parameterization can be subsumed into U), for some $Q \in \ell_1$. Furthermore assume that the transfer function $\hat{U}$ has no zeros on the unit circle with all its unstable zeros (which are zeros inside the unit disc) $z_1, z_2, \dots, z_n$ distinct. Let*

$$A = \begin{pmatrix} 1 & z_1 & z_1^2 & \dots \\ 1 & z_2 & z_2^2 & \dots \\ \vdots & \vdots & \vdots & \vdots \\ 1 & z_n & z_n^2 & \dots \end{pmatrix}, \quad b = \begin{pmatrix} \hat{H}(z_1) \\ \hat{H}(z_2) \\ \vdots \\ \hat{H}(z_n) \end{pmatrix}.$$

Then

$$\begin{aligned} & \{ \Phi : \Phi = H - U * Q, Q \in \ell_1 \} \\ &= \{ \Phi : A\Phi = b, \Phi \in \ell_1 \}, \end{aligned}$$

where $A\Phi = b$ denotes the n constraints $\sum_{k=0}^{\infty} \Phi(k)z_i^k = \hat{H}(z_i)$ for $i = 1, \dots, n$.

Thus

$$\begin{aligned} v &= \inf_{\Phi} \{ \|\Phi\|_{\ell_1} : \Phi = H - U * Q, Q \in \ell_1 \} \\ &= \inf_{\Phi \in \ell_1} \{ \|\Phi\|_{\ell_1} : A\Phi = b \}. \end{aligned}$$

Proof. A sketch of the proof is provided. Note that $\hat{\Phi} = \hat{H} - \hat{U} \hat{Q}$ implies that $\hat{Q} = \frac{\hat{H} - \hat{\Phi}}{\hat{U}}$. Evidently, $Q \in \ell_1$ implies that the unstable zeros of $\hat{U}$ are cancelled by the zeros of $\hat{H} - \hat{\Phi}$ which in turn implies $\hat{\Phi}(z_i) = \hat{H}(z_i)$ for all unstable zeros, z_i , of $\hat{U}$. Thus for $\Phi \in \ell_1$ with $A\Phi = b$, a $Q \in \ell_1$ can be obtained such that $\hat{\Phi} = \hat{H} - \hat{U} \hat{Q}$. This completes the sketch of the proof. $\square$
